Total			1.5

1 Not detected.

Measurements of cesium 137/potassium 40 ratios in milk during 1956 (fig. 7) indicated peak activities resulting from periods of tropospheric fallout. The relative effect of such increases in foodstuffs on the cesium 137 level in people can be estimated from the simple model shown in fig. 9. A step function change in the foodstuff level will be followed by a $(1-e^{-\lambda t})$ change in the population level (where λ is the biological elimination rate), and a new equilibrium value will be reached only after an elapsed time of the order of 1 year. If the foodstuffs return to their previous value before equilibrium is attained, the population level will cease rising and will decay back to its previous value with a halftime corresponding to the biological elimination rate.

This model can be applied to the situation during July and August, when the level of cesium 137 in milk rose by about a factor of 3. Since not enough data are available to define completely the shape of the peak, and since milk values are used as representative of all foodstuffs, the actual peak can be replaced with a step function of the same approximate area. This gives a rise of about 2 times "normal" for a period of 50 days. In this case, the maximum rise in the population level, predicted on the basis of the model in figure 9, is 20 percent. Using the average value of the cesium 137/potassium 40 ratio for the control subjects in the spring of 1956 (fig. 3) of 0.4, their calculated ratio 6 months later is 0.5. The observed summer maximum average was 0.48, in agreement with the model.

An estimate of the biological halftime of cesium 137 in the chronically exposed case was obtained by counting a large urine sample representing 52 man-days of excretion. The sample showed 408 disintegrations per second of potassium 40

(136 grams of potassium) and 40 disintegrations per second of cesium 137. Assuming an average body burden of 0.005 microcurie of cesium 137 for the 6 subjects who contributed urine samples, the excretion rate is 0.004 per day, which corresponds to a halftime of some 180 days if the excretion is exponential and entirely urinary. If fecal excretion is 25 percent of urinary, the halftime would be 145 days. This is in agreement with the biological halftime of 140 days observed on volunteers who ingested 1 microcurie of radiocesium (9).

Using Bureau of Agriculture statistics for food consumption per capita in the United States (22) and our preliminary values for the average cesium 137 content of foodstuffs, the dietary intake of cesium 137 can be estimated (table 2). On the basis of these data, it appears that milk contributes about 50 percent and meat about 25 percent of the cesium 137 found in the body. The excretion rate of cesium 137 can also be estimated from these intake data. This method is only an approximation because of uncertainties in diet and in the average cesium 137 level in the various dietary components. According to the data in table 2, the turnover rate is of the order of 1.5 millimicrocuries per month, compared with the observed value of 0.6 millimicrocurie. Part of the discrepancy may result from using retail weights in computing the diet with no allowance for wastage and loss of minerals in cooking, but the principal source of error is probably the inadequacy of our knowledge about cesium in foodstuffs. For comparison, a similar computation was made for potassium (table 3). The calculated potassium intake is about 3 grams per day, while the observed urinary excretion was 2.6 grams per day. Elkinton and Danowski (23) reported potassium turnover as falling in the range of 2 to 6 grams per day.

TABLE 3.—*Calculated potassium intake based on per capita food consumption*

Source	Consumption (lb./mo.)	Potassium	
		Content (g./lb.)	Intake (g./mo.)
Dairy products	5.8	6.0	35
Meats	11.4	1.2	14
Flour and cereal	13.0	.5	6
Vegetables	16.8	1.0	17
Citrus fruits	3.2	1.0	3
Potatoes	8.8	2.0	18
Total			93

While the spring 1956 average value for the cesium 137/potassium 40 ratio in milk was 0.25, the average in people for the corresponding period was 0.4. This difference may be explained on the basis of the longer holdup time of cesium in the body as compared with potassium. If q_{cesium} is the amount of cesium in the average daily diet, and $q_{potassium}$ is the corresponding amount of potassium, then $q_{cesium}/q_{potassium}$ is the cesium/potassium ratio for the average diet. The milk ratio can be used since it is the most important single factor and is the only one known with any accuracy. The equilibrium amounts of cesium and potassium in the body, on the basis of the simplest model, will be given by the product of $q\tau$ for each element, where τ is the mean life of the element in the body (24). For cesium, τ has been determined to be 200 days; τ for potassium can be estimated from our data on the potassium content of normal urine as about 58 days. Thereforce, cesium should be concentrated relative to potassium by a factor of 200/58, or 3.4. If the average diet ratio is 0.23, the predicted ratio in people is about 0.8. This is too high by a factor of 2.

Libby (4) has estimated stratospheric injection by Operation Redwing at about 6 megatons of fission products in addition to the 18 megatons left from the previous operations. This would imply a 30-percent increase in the fallout rate from the stratospheric (worldwide) component after the tropospheric component is gone. A comparison of the spring and autumn milk averages indicates no detectable increase in the fallout rate. The spring sampling was inadequate; hence there is considerable uncertainty about the proper average. However, it would appear that, if anything, the cesium levels in the fall were lower. This may be a seasonal variation resulting from the change from pasture to hay feeding of the dairy herds, which would conceal possible small increases.

SUMMARY

Measurements of the cesium 137 content of people and of foodstuffs indicate that this nuclide is unlikely to be a decisive factor in the long-term hazards from weapons testing and reactor waste disposal. The amount of cesium 137 now present in the population of the United States averages 0.006 microcurie and shows no marked dependence on geographic location. The average radiation dose received from cesium 137 is one-twentieth of that received from natural radiopotassium and 1 percent of the average total dose from all natural sources. Because of the short biological half-life of cesium of about 140 days, it does not accumulate in the body as does strontium 90. The study of the distribution of cesium 137 is being continued to furnish information on the mechanisms of the fallout process and provide a measure of the rate of fallout and of stratospheric storage.

STATEMENT SUBMITTED TO THE JOINT COMMITTEE ON ATOMIC ENERGY BY L. D. MARINELLI [1] AND J. E. ROSE,[2] RADIOLOGICAL PHYSICS DIVISION, ARGONNE NATIONAL LABORATORY, LEMONT, ILL.

TOPIC IX. OCCURRENCE OF CS-137 IN THE ATMOSPHERE, BIOSPHERE, AND ITS UPTAKE AND BEHAVIOR IN MAN

The fission product Cs-137 is produced with a yield of about 6 percent and it has a half life of about 27 years. The general characteristics of its distribution and behavior in mammals, as reported by several authors (1-4), indicates only a partial qualitative similarity to potassium. Important from our standpoint is the fact that cesium is excreted by humans at a rate lower than potassium. This leads to a Cs/K ratio in vivo which is from 2 to 3 times the ratio in the ingested food.

Because of its gamma-ray emission, Cs-137 can be measured in the living animal and in bulk material without recourse to lengthy chemical analysis.

To make these measurements, it is necessary to shield both instrument and subject from the radiation emitted by ordinary building materials. This is done by performing the tests in an 8 by 8 by 6 foot room with 8-inch steel walls, weighing 60 tons. This room consists of a bolted frame of angle beams upon which one-quarter inch plates of 12 to 26 inches width are placed in staggered sequence on all sides in order to avoid continuous cracks in the walls. The side plates are held in place by clamping them together between the frame and appropriately placed angle irons.

Gamma-ray radiation emitted by the subject impinges on an 8 inch by 4 inch NaI crystal; the electrons liberated therein produce scintillations which are amplified by a photomultiplier tube and registered, according to their sizes, by a 256-channel analyzer. From the scintillation spectrum it is possible to identify the energy of the gamma radiation (hence the radioelement responsible for it) an dits intensity (hence the amount of material involved). Presently this apparatus has a sensitivity greater than 10^{-9} curies of the gamma emitters under discussion in the intact human subject.

In the summer of 1955, at the Argonne National Laboratory, measurements of the total body gamma-ray activity of members of our staff, visitors from various parts of the country and from overseas, local medical students, etc. (5), disclosed the presence of this radioelement in all of the test subjects. Since then, continual tests on a group of 12 people, has shown an increase in the human burden by a factor of about 2 up to the spring of 1956, and a constant value thereafter, corresponding to about 3.2×10^{-11}C of Cs-137 per gram of potassium (fig. 1). Contrasted to the findings for Sr-90, children do not exhibit high concentration per unit weight.

No correlation between Cs-137 content and geographic origin of the subject was noted (table I). On the other hand, the dependence on the dietary habits of the individual (fig. 2) became evident after a study of the Cs-137 content of food and water. These revealed that bovine meats, milk and milk products constitute the main routes of intake (fig. 3). Subsequent confirmation of these findings on larger representative samples of people and foodstuffs have been obtained at the Los Alamos Scientific Laboratory (6). The observations to date

are consistent with the concepts of (*a*) stratospheric storage, (*b*) constant deposition on grazing lands, (*c*) uptake by cattle, and (*d*) transmittal to man.

Other relatively abundant and long-lived fission products, i. e., Ce–144—Pr–144 (290 day), Zr–45—Nb–95 (63.3 day), and Ru–106—Rh–106 (1 year), easily detectable by our technique in laboratory air, dust, sweepings from house carpets (fig. 4) and soil (7) are not present in the intact mammal in measurable quantities. These findings are consistent with previous observations on their low intestinal absorption following oral intake by laboratory animals (3).

In its present concentration, Cs–137 contributes on the average less than 0.3 mrad to the yearly dose of over 150 mrads which a human being is reported to absorb from natural sources of radiation (fig. 1).

Because of its relatively short life in the cow and of its reputed unavailability to the roots of some plants,[8] the concentration of this radioelement in milk is likely to serve as an excellent indicator of average rate of fallout over milk sheds. Since we can measure directly its presence in the living human we need not rely on theoretical predictions as to the possible individual variations under various conditions. Thus, only a factor of 6 separates the lowest values found in oriental subjects (whose diets are practically devoid of cattle products) to the highest found in the United States of America in an individual on a milk diet.

Pertinent to this discussion and to item X of the agenda are our recent findings on some inhabitants of the Marshall Islands which were measured in our facility by Dr. C. E. Miller. The scintillation spectra are shown in figure 5, and the body contents are included in table I. It should be noted that subject No. 10 is a control living in Majuro Island which did not experience unusual fallout. The next four subjects were inhabitants of Rongelap removed more or less permanently from that island to Majuro Island because of heavy fallout. Their content of Cs–137 is about 2 or 3 times that of the average United States citizen. The reason for this cannot be stated at this time but consumption of coconuts (reputed to acquire Cs) may be implied. The presence of Zn–65 in their body is due to contamination of seafood.

The highest contents of both Cs–137 and Zn–65 were found in subjects Nos. 5 and 18 who were removed temporarily from the island of Uterek because of heavy fallout and returned there after appropriate decay of the external radiation. It is obvious that they represent burdens likely to be acquired by living in zones of relatively high levels of contamination. Yet, despite these circumstances the increased dose rate of radiation to which they are exposed is only a fraction of the normal background of 100 to 160 mrads per year.

Senator ANDERSON. Dr. Kulp, Dr. Eisenbud, and Dr. Neuman, do you and Colonel Hartgering want to get into some questions here, back and forth, that would be helpful to all of us? Dr. Langham, we would like to have you in it also.

Mr. Neuman, do you want to kick off on any comments you may have on the afternoon presentation?

DISCUSSION BY DR. J. L. KULP, MERRIL EISENBUD, DR. WILLIAM F. NEUMAN, DR. WRIGHT LANGHAM, AND COL. JAMES B. HARTGERING

Dr. NEUMAN. I would rather sandbag, if I may.

Mr. RAMEY. It might be desirable if Dr. Neuman could sort of state his case. Some of the members were not here and Dr. Kulp was not here at the time either.

Dr. NEUMAN. As a brief summary, I think it best to say that, in my opinion, the very best evaluation of future levels of bone are those calculated from our equilibrium data on natural strontium because this involves only one assumption; strontium behaves like strontium.

It is also my opinion that the natural strontium data in England and the bulk of the experimental data available in this country indicate that the overall discrimination from ground to bone is about a factor of 8. With this number, one has a fixed relationship between ground level and bone level. If we choose a certain maximum level to be permitted in human bone, we automatically fix a maximum level that can be permitted on the ground. With this number one can calculate the maximum rate at which testing can produce fission

products. The testing rate can be 2½ percent of the permissible ground levels.

Using a rather arbitrary set of numbers, the maximum permissible level of 50 sunshine units, which is one of the several levels that have been suggested, the test rate comes out to be a rather small number of the order of 2 megatons of fission equivalent per year.

I think that is a fair summary.

Senator ANDERSON. I think what perplexes a great many of us is that Dr. Langham wrote down a great number of figures and they all were pretty much in agreement—2.5, 3.1 at Los Alamos, 4.1 from Dr. Eisenbud, 3.5 from the milksheds—those figures are very close, very accurate, and apparently we have come to some sort of agreement.

Do you agree that it is going to take a hundred years of testing to get to the point where there is some danger to it if we continue at just the present level?

Dr. NEUMAN. I don't see how anyone could make a prediction concerning how long it would take because one has to assume a test rate.

Senator ANDERSON. I tried to say at the present level of putting fission products into the atmosphere. I am trying to get some fixed term if I can use it. If that is not a correct one I am sure Dr. Langham can give me a better one.

Dr. NEUMAN. I am not clear what present level of testing has been assumed. I take it to be based on measurements up to the fall of 1956.

Dr. LANGHAM. It has averaged roughly 10 megatons for 5 years.

This does not include anything that the Russians and British have done in the last few weeks.

Senator ANDERSON. I think that is useful. Can we all use that same figure and say we will assume, regardless of whether it is accurate or not—let us assume it is accurate, and I think it is probably very close—that we have been putting 10 megatons of fission products into the atmosphere each year for the last 5 years. Suppose we continue at that clip for the next 20 years, Dr. Neuman would you think that we had reached the maximum permissible level after 25 years or something of that nature?

Dr. NEUMAN. I should think it would be of the order of 25 years. Actually it would be a million years before you achieve true equilibrium. But for practical purposes, 25 years would be a reasonable number. It depends upon the MPC.

Mr. EISENBUD. 50 would probably be best.

Dr. NEUMAN. I agree, if the MPC is taken as 100 sunshine units.

Senator ANDERSON. Dr. Kulp, what do you think.

Dr. KULP. I don't think I am competent to say when there is a hazard. This is what you must get into next week. As far as the levels are concerned, it looks like there is only about a factor of 2 or 3 difference in the way Dr. Neuman and I calculated this thing. He used 50 instead of 100 as the safe level, and he used a factor of 10 from the soil to bone.

Dr. NEUMAN. Eight.

Dr. KULP. Yes; eight. I did not base it on the soil because I do not believe that the strontium 90 is ever going to be homogeneously distributed all the way through the soil, which is the condition you must have to get his 8 and 10 figure. This is based essentially on dividing

the milk value by 2. I end up with a practical soil to bone value of closer to 20. You can take your choice on these two things. That is the way they are derived. It depends on whether or not the strontium 90 becomes homogenized throughout the whole earth column.

Senator ANDERSON. Dr. Eisenbud.

Mr. EISENBUD. Mr. Chairman, I would like to supplement the remarks I made earlier today. I predicted a maximum of 5 micromicrocuries per gram from the tests to date. If we assume that the testing rate is going to continue as it has in the last 5 years, then the maximum instead of being 5 would be about 40, sometime after the turn of this century. If I superimpose a factor of 3 that Dr. Neuman used in order to allow for individual biological variation—and I am not sure this is necessary—then I arrive at a figure of 120 micromicrocuries per gram. This suggests that if we are going to continue testing until the year 2020 and if we are going to limit the maximum to Dr. Neuman's figure of 50 micromicrocuries per gram, then we are going to have to reduce the testing rate to one-third of the rate for the past 6 years.

Senator ANDERSON. You now say, if I can try to tell you what is in the minds of some people, that if we can continue the test to the year 2020 and if these other factors continue, and I am not trying to bind anybody to them, then we will have to cut down the testing by a factor of 3. That brings it down to 3 megatons of fission products to be discharged each year. We say if we are going to continue as we are now going, when will we reach an extremely dangerous position? Will that be 40 or 30 years?

Mr. EISENBUD. I was going to get to that, Mr. Chairman, and summarize by saying that at the rate information is accumulating we will have the answer long before the hazard develops. We are talking in terms of hazards developing at the present rate in terms of tens of years. We are accumulating significant information from month to month. Whether or not this factor of 3 should be included I think is something that will be known in the next year or so. We will not know everything we would like to know in the next few years, but we will learn enough to eliminate many uncertainties in calculations of the type Dr. Neuman has described.

Senator ANDERSON. Doctor Kulp.

Dr. KULP. I should like to emphasize that I agree completely with Dr. Langham's analysis that the big uncertainty is in the biological hazard where you are going to set the level. This factor of uncertainty of 3 in the distribution should be very firmly fixed within another year at the rate at which data is coming in. This is just a matter of getting an adequate number of samples at the right locations and measurements betwen the bone analysis and the anlaysis of the total fallout that Dr. Eisenbud's group is doing. That will not be important with regard to uncertainty a year hence.

Senator ANDERSON. Dr. Langham or Colonel Hartgering, do you have a comment there?

Colonel HARTGERING. I guess I am the only physician in the group. I don't like to leave the impression that we will know what the somatic relation will be in man. You do not get that in a couple of years. The bone samples and soil samples are coming in rapidly. The type of work I discussed we are doing at Reed. This is obviously continuing, but the somatic effects on man and what this means in terms of injury to him is not going to be available in the next year or two.

Senator ANDERSON. Suppose we should get to another assumption now. Suppose we should say that since other countries are developing weapons that we now raise this rate from 10 megatons of fission products a year to 20 megatons. Would that accelerate pretty rapidly in the time when we might reach these dangerously high levels or what we might assume to be?

Dr. Langham, would you care to comment?

Dr. LANGHAM. I think this borders on something that is more in your field than in ours. What it really amounts to is this: About 10 megatons per year total testing by everybody seems to be just about as much as one would assume we should allow.

Senator ANDERSON. That is a very important and very fine statement. That is one of the things we were trying to get in this hearing, and I am so happy to have it from you, because I know you have spent a great deal of time on it. I am going to try to find out how many people agree with you in a short time. Regardless of agreement, the fact that we bring a figure out on the table and talk about it I think is extremely important because it does indicate your belief, and I think the belief of a great many others that if 10 megatons of fission products is about what we should put in the atmosphere each year, then maybe there is some need to find out what the other people in the world are doing and see if we can hold at that figure.

As you know, I strongly support the idea of constantly improving and testing the devices that we have. I have been very happy at the work at both Los Alamos and Livermore in making these tests possible with as little disturbance to our strontium 90 pictures as possible. Therefore, I am very happy to have this figure from you. You were going to say some more but I did want to break in to say that this is one of the things many people have been hoping to hear from somebody in authority.

Dr. LANGHAM. The implications of this are, of course, that we are no longer the only people testing weapons, which leads automatically to the idea that what one really needs is some type of international agreement with regard to an allocation of fission products that can be injected. Such an arrangement would not place a limit on the total megatons tested but the amount of fission that could be injected into the atmosphere.

This would lead to an encouragement of people to build cleaner weapons or to explode them under conditions which would allow less material to go into the biosphere. The only way one could monitor this would be to get an agreement whereby they would put a tracer on each bomb which would allow anyone in the world to sample their cloud and tell what fraction of the cloud they tested. Then we could monitor how much each country was putting into the biosphere.

The only thing is that in so doing we would gain a lot of information about their bombs which would, of course, mean that it would be hard to get an agreement on such a point.

Senator ANDERSON. Thank you very much. Dr. Eisenbud, we would be glad to have you comment on this upper limit that we have tentatively placed on what we can do. It is a very interesting figure.

Mr. EISENBUD. I think, to use a colloquialism, "We are in the right ball park."

I am also impressed with the fact that the proposed limit is approximately of the same order of magnitude as they assumed the past test-

ing rate. I note that we are talking about reaching the so-called maximum permissible limit, not in terms of months or years but in decades. This suggests that one can feel comfortable that the emergency is not here. We are talking about a hazard that may develop many years from now. We will have ample time to study the problem.

Senator ANDERSON. Dr. Neuman, I would be very happy if you would comment on Dr. Langham's number a moment ago. I hope this is not embarrassing to you.

Dr. NEUMAN. I should say, at the outset, that I am amazed. I felt very lonely up there when I was giving my testimony. Now I find we really are not so different in our predictions after we used our pencils.

Senator ANDERSON. I think that is true generally of scientists when they get together in discussions. That is one of the reasons of having many scientific discussions. That is one of the reasons why the chairman of this committee and the chairman of the subcommittee were anxious to get scientists in here to testify in a fine scientific fashion.

Dr. NEUMAN. It was not very long ago for lack of data that we were swinging rather wildly. The data that have come in recently have sharpened the arena of debate to the point where, as I indicated at the outset, I did not feel we were in trouble, that the present levels are indeed low. This has been stressed many times. It probably needs no further emphasis.

On the other hand, the rates of permissible testing have now narrowed down to somewhere between 2 and 10 megatons per year of fission products released. I think the most important aspect is not whether it is 2, 4, 6, or 10, but the fact that it is a small and finite number, one small enough that we can right now envision an international agreement, as Dr. Langham has indicated, and at the same time, as Merril Eisenbud has indicated, that we can approach this without a scare—or fear—psychology, that there is sufficient time to draw sane and careful agreements embodying necessary precautions so that these agreements can be enthusiastically endorsed. We are really uniquely in a good position knowledgewise to affect an effective ban.

Senator ANDERSON. Thank you. Can 1 of the 5 of you help me on a matter? The statement was made that it might take a hundred years to reach a high level—a hundred years of steady testing—and yet the strontium 90 has a half life of 28 years. How do I try to relate those two things?

Dr. Langham, can you help me?

Dr. LANGHAM. What this means, sir, is that if strontium 90 is decaying with a half time of 28 years, then in about a hundred years we will have shot—or if you want to take Dr. Libby's number, about 50 years—into the biosphere enough strontium 90 so that it is decaying at the same rate we are testing. We will be at equilibrium and we can test for the next 2,000 years supposedly and it would not increase a great deal more.

Senator ANDERSON. I think you explained that to me once before but I wanted to get it in this record.

Dr. Kulp, do you have any comments?

Dr. KULP. I think the only point I would like to add is that in considering this 2 and 10 that we are still shooting at this 100 number. Taking the radical view for just a minute, I wonder if we are fair in multiplying our values times 3, to be very safe, and comparing this

with a hundred when already we have dropped this to a hundred for an average general population. I think the radical might still say we might be allowed 30. The conservative might very well say that 2 would be about 200 times too much. But this will come out next week.

Chairman DURHAM. Doctor, what is that 100 based on? Is that based on medical statistics or what is it based on? Did you just pull the 100 out of the air?

Dr. KULP. I think Dr. Langham should answer that.

Dr. LANGHAM. You were asking about the 100 micromicrocuries and what is it based on?

Chairman DURHAM. Yes.

Dr. LANGHAM. The way it was derived is as follows: We have had a certain amount of experience with radium in people. We think we have a good idea that one-tenth of a microcurie of radium fixed in the bone for essentially one's lifetime will do him no harm. Therefore, we have picked that amount of strontium 90 which would give the worker the same amount of radiation that was given to these people who had a tenth of a microcurie of radium.

So we have said for our occupational tolerance we will take that amount of strontium which is equal to the maximum permissible level of radium. For the world population or for the unoccupied people in this particular pursuit, we will take one-tenth of it. One-tenth of this value which has been selected in comparison with radium is equivalent to the 100 micromicrocuries per gram of calcium in the bone.

So it is based on comparison with radium and our experience in the radium industry. It assumes, sir, that the response to radiation is a threshhold effect. Whether or not radiation is a threshhold effect is not clearly yet established. In fact, the general tendency is to look at long-term changes following radiation damage, including genetics, as being the linear type and not the S-shaped curve I drew on the board. It turns out that 100 micromicrocuries of strontium on the average is about equal to the natural background that we get to the bone.

You can go on from his. As Dr. Lewis has just done in a recent excellent article in Science, you can tie this to the leukemia incidence in the world and you can go ahead and make postulations which will allow you to postulate how many cases of leukemia this may mean distributed throughout the world population. But in order to make that comparison you must assume that you know the effect of radiation or that the increase in radiation damage is linear with increasing dose, and not a threshold response.

Next week is going to be a very interesting session because it is primarily to bring out these very points.

Senator ANDERSON. Very well said, and a fine statement. I thank you for it.

Are there other observations that anyone wants to make?

If not, I would like to ask you if you would sort of document these "chalk talks" as much as you can to us so when we select certain portions for reproduction we may be able to add to it a little bit the bases upon which these decisions were reached, just as you have done here.

May I therefore announce that the hearings will resume on Monday, June 3, and continue through Friday, June 7. June 11 and 12 have

been reserved for testimony from scientific experts who wish to appear but who are not taking part in the first 2 weeks' discussions. The Monday meeting will be in this room.

Just in closing, may I say it has been a real privilege to have such a fine panel for this work today.

Chairman DURHAM. I would like to add my appreciation, too. It certainly has been a fine discussion.

Senator ANDERSON. Thank you very much.

We are adjourned.

(Thereupon, at 4:15 p. m., Wednesday, May 29, 1957, the hearing was recessed, to reconvene at 10 a. m., Monday, June 3, 1957.)

THE NATURE OF RADIOACTIVE FALLOUT AND ITS EFFECTS ON MAN

MONDAY, JUNE 3, 1957

CONGRESS OF THE UNITED STATES,
SPECIAL SUBCOMMITTEE ON RADIATION
OF THE JOINT COMMITTEE ON ATOMIC ENERGY,
Washington, D. C.

The special subcommittee met, pursuant to recess, at 10:10 a. m., in the caucus room, Senate Office Building, Hon. Chet Holifield, chairman of the subcommittee presiding.

Present: Representatives Holifield, Durham (chairman of the Joint Committee), Price, Dempsey, Van Zandt; Senators Anderson, Hickenlooper, and Bricker.

Also present: Professional staff members: James T. Ramey, executive director; George E. Brown, Jr., Hal Hollister, staff technical adviser, and Paul C. Tompkins, consultant.

Representative HOLIFIELD. The committee will be in order, please.

The hearings have covered up to now sections I through IX of the outline. This includes background information on the nature of radioactivity, the production of fallout by the detonation of weapons, its transport in the atmosphere, and its deposition and uptake in animals and man. We spent a good deal of time on local and delayed fallout and began our investigation of the main culprit, strontium 90. Many subjects that initially appeared to represent marked disagreement have developed into subjects on which there is general agreement when put into perspective.

(*a*) The radioactivity from fission products is considerably more dangerous than the radioactivity induced in the environment by neutrons. Furthermore, a radioactivity "clean" weapon device is apparently not possible.

(*b*) The way radioactive materials are introduced into the biosphere is subject to wide variation with air detonations favoring wide dispersion and surface detonations favoring local fallout. For estimating how much material is injected into the stratosphere the consensus figure is about 50 percent, although RAND and others feel that 20 percent is a better figure for detonations over land. The distribution of worldwide fallout appears to be nonuniform. Variation from the average by more than threefold, as far as long-range deposition is concerned, does not appear to happen.

(*c*) The depositions from fallout to date in the biosphere including uptake in man is apparently low—approximately 10 percent—when compared to natural radioactivity. The significance of this fact has yet to be discussed.

93299°—57—pt. 1——50

(*d*) Discrimination between calcium and strontium in biological processes does occur.

(*e*) The rate at which knowledge of the food chain processes is accumulating leads to confidence that serious trouble from fission products can be foreseen in advance.

(*f*) On Wednesday, May 29, there was a concensus of qualified witnesses that fallout was hazardous to a degree, and that some limitation on the injection of fission products from all sources into the atmosphere was desirable. There were differences of opinion as to this limit, with the highest fallout limit being placed at the rate of 10 megatons of fission yield per year.

(*g*) The critical scientific issue in the strontium 90 controversy was identified as the determination of whether or not the dose-effect relationship is linear or has a value below which it produces no effect, that is, a "threshold." This subject is to be covered this week, starting this morning.

This is a brief summary of the testimony as prepared by the scientific members of our staff.

There was some confusion in the testimony regarding the units of measurement for radiation, and we have changed the order of witnesses this morning. We are going to have Mr. Lauriston Taylor, who is head of the Atomic and Radiation Physics Division of the National Bureau of Standards, testify this morning on this particular subject.

Mr. Taylor, will you please come forward and take the chair on the right?

Mr. TAYLOR. May I use the podium?

Representative HOLIFIELD. Yes, you may use the podium.

STATEMENT OF LAURISTON S. TAYLOR, CHIEF, ATOMIC AND RADIATION PHYSICS DIVISION, NATIONAL BUREAU OF STANDARDS [1]

Mr. TAYLOR. Mr. Chairman, thank you very much for the privilege of appearing before you.

I am the head of the Atomic and Radiation Physics Division of the Bureau of Standards.

Representative HOLIFIELD. Thank you, sir.

Mr. TAYLOR. The material that I have to cover this morning is rather extensive, if one goes into detail. In order to save time, I would like, with your permission, to insert some dozen and a half

[1] Date and place of birth: June 1, 1902, Brooklyn, N. Y. Education: Stevens Institute of Technology and Cornell University. He joined the staff of the National Bureau of Standards in 1927. With the exception of the periods 1943–46, when he served overseas with the 9th Air Force as Chief of Operations Research Section, and in 1948, when he was loaned for 1 year to the AEC as Chief of the Biophysics Branch, Dr. Taylor has been engaged in the NBS research and development programs in radiation physics. Chairman of the International Commission on Radiological Protection from 1937 to 1950, adviser on the United States Delegation to the International Conference on the Peaceful Uses of Atomic Energy at Geneva, Switzerland, in 1955. Chairman, National Committee on Radiation Protection and Measurements; consultant, Department of Defense Weapons Systems Evaluation Group; member of the American Medical Association's council on physical medicine; National Research Council's committee on nuclear science, and the subcommittee on radiobiology; the National Academy of Science's advisory committee on civil defense, etc. Gold Medal of Radiological Society of North America for leadership in field of radiation protection on national and international scale; Janeway Medal of American Radium Society for contributions toward development of international standards for radiation protection and radiation units; Sylvanus Thompson Medal from British Institute of Radiology; Bronze Star Medal (1945), Medal of Freedom (1946) for services for the Air Force. (Submitted by the Department of Commerce.)

pieces of material into the record, and also, if it is agreeable to you, I will refer to these by number as I go along. I have supplied the stenographer with a list of these, and this will save the time of having to read each title fully.

Representative HOLIFIELD. Without objection, that will be the order of the committee.

Mr. TAYLOR. Thank you.

The main purpose of this part of the discussion is to give some general background for our radiation units, and the standards of radiation protection, and to indicate some of the areas of certainty or uncertainty, and some of the areas where we know things with reasonable certainty. At the same time, I think it would be worth while in this connection to indicate some of the areas of research needs that will be fairly obvious from my discussion.

Until about 1928, any protective measures that we may have had were purely on a guesswork basis, and the reason for this was that until 1928 we had no acceptable unit of radiation dose. In 1928 there was international agreement on a unit of dose known as the roentgen. Once this unit had been decided upon, it was then possible to go forward with the establishment of quantitative radiation dose units for protection purposes.

Now, the roentgen was the only unit of radiation dose until the early 1940's. In fact, it was the only unit for which there was any use, because, for all practical purposes, we had only to deal with radiation from radium and X-rays, and the unit "roentgen" applies only to gamma rays and X-rays.

So in that early period, the formative period of our radiation protection philosophy, we dealt entirely with the roentgen as the unit. It is still a completely acceptable and useful unit of exposure dose, with certain limitations. However, one should not speak of the dose from all radiations in the terms of roentgens. This, unfortunately, has been somewhat the practice, at least in public writing. I think the scientists in general keep these matters straight.

Because we had other types of radiation to worry about beginning in the forty's, particularly large quantities of beta rays, neutrons, alpha rays, and so on, it was necessary to have another unit which could measure all of these radiations in equal terms, and for that purpose in 1953 the International Commission on Radiological Units adopted another unit known as the rad.

The "rad" is a unit of absorbed dose. It tells you how much energy has been imparted to tissue from any of the radiations in question. It is still a difficult quantity to measure directly. A considerable amount of further developmental work on this is certainly required, and I will come back to some of that later.

When we are talking about dose, there is another term that enters our thinking, and this is known as "dose rate," and dose rate is, as its name implies a rate of giving dose.

Perhaps to give an example to illustrate this, let us consider a dose of aspirin. One tablet of aspirin could be called dose, and when you have taken this 1 tablet you have had a dose of 1 tablet of aspirin. Now, a doctor could tell you that he wanted you to take a dose of eight tablets. If you take all of these eight tablets at once, you are probably going to be in some sort of medical difficulty. So you distribute them,

and he will tell you to take these 8 tablets at the rate of 1 per hour or 1 every 2 hours, thereby introducing into the dose the time concept. Certainly, in the case of aspirin, it makes a lot of difference whether you take the whole eight tablets of aspirin at once, or whether you distribute them over a day, or over a week.

This time distribution may or may not be important, depending upon the circumstances, when we are talking about radiation.

There is another unit that has been referred to in previous testimony called the "rep." This was a unit that was invented for practical purposes during the Manhattan District days, and was designed to establish some relationship between the dose that is given by different kinds of radiations. The difficulty today with the rep is that it has been variously redefined many times to the point where nobody is really certain as to what is meant when he speaks of the rep.

The value for the rep of 93 ergs per gram—that is, the energy that is absorbed by 1 rep of radiation—was mentioned in earlier testimony. All I can say is that 93 ergs per gram is not considered to be a good value for the rep, and the hope is that this term will gradually be discontinued.

There is another term that we will hear a great deal about, I suspect, in the next 2 or 3 days, known as the RBE, or the relative biological effectiveness of radiation. The RBE is a factor that is used to equate the biological effects of different kinds of radiation, such as alpha, beta, gamma rays, X-rays, neutrons, and so on. These act differently on tissue because of their physical characteristics, and it is not readily possible to compare the effect of these different radiations without some kind of a comparison factor. There is considerable uncertainty about the values of the RBE for many radiations, and this will come out in later testimony.

The relative biological effectiveness of two different radiations depend on a great many factors. It depends on the particular organ in the body that you are investigating, the kind of effect in that organ, the absorbed dose that is given to that organ, the rate of delivery of the dose, the way the dose is fractionated between exposures, the pH and oxygen content of the tissue, the temperature, and other factors. At the present time the RBE is known only roughly in some of the areas that must be regarded as quite important. Here is an area where a great deal more research is certainly called for.

I might remark at this point that the National Committee on Radiation Protection in this country, and about which I will tell you more later, has a subcommittee working actively on the whole question of RBE. This program is under the chairmanship of Dr. Wright Langham, who testified before you the other day, and is being supported in part by the Atomic Energy Commission in its program at Los Alamos.

In this program they are presently compiling and correlating a vast amount of data that is pertinent to this question. We hope they will develop the specific areas of need, and thereby direct attention to them, so that the necessary research and development can be carried out to fill any gaps.

I might point out at this time that our lack of knowledge of the RBE, the relative biological effectiveness of the different radiations, is not as far as we are aware, introducing what one might call danger factors in the setting of our permissible exposure levels. It is possible

to make some kind of upper and lower estimates, of the RBE values, and where there is any doubt the higher value is chosen. This is erring on the side of providing more protection than your basic numbers might initially indicate.

On the other hand, it is important to take advantage of the proper values of the RBE when you know them, because, if you use values that are too low, it makes protection very costly and this, in turn, reacts unfavorably on the development of nuclear energy programs.

There is still another unit that I will use, and others will use considerably as time goes on, and this is known as the rem.

The "rem" is what we would call a unit of RBE dose. It essentially includes all of the factors that we know about dosimetry. It includes the RBE, and the absorbed dose in rads; and if you want to talk in completely general terms about radiation, you can refer to radiation dose in rems for all radiations, and for all conditions, bearing in mind that where you have an uncertainty, for example, in RBE's you also have an uncertainty in RBE dose.

Another unit that has been talked about is the curie. Now the curie is not a unit of dose, it is a unit of quantity of radioactive material. It essentially tells you how much material you have, and it is related to the number of radioactive disintegrations that occur in a given time in a radioactive material. It is really more comparable, you might say, speaking loosely, to a unit of weight. In fact, for radium, 1 curie is equal to 1 gram of radium.

One other unit that has been talked about is the sunshine unit, it is based on the maximum permissible body burden of strontium. Where we have set for occupational purposes a permissible body burden of one microcurie of strontium, this means one microcurie of strontium for the whole body. Since there are approximately a thousand grams of calcium in the whole body, so it means one microcurie of strontium 90 per thousand grams of calcium. When you go through the arithmetic, this would turn out to be a thousand micromicrocuries of strontium per gram of calcium.

Now the sunshine unit, I believe, relates primarily to the body burden for people not occupationally exposed. Those levels are considered to be one-tenth of the levels for occupational exposure. So one sunshine unit would then be one one-hundredth of the average permissible body burden for the general population.

A word as to the status of the units. On the whole I think it can be said that they are fairly well in hand.

Representative HOLIFIELD. Excuse me, Doctor; was there any scientific reason why the word "sunshine" was used in this instance?

Mr. TAYLOR. The term "sunshine" itself?

Representative HOLIFIELD. Yes.

Mr. TAYLOR. There may well be, but I am not aware of it.

Senator ANDERSON. Did it not grow out of the fact it was called "Project Sunshine"?

Mr. TAYLOR. I suspect this is the source of the name; yes. I do not think there is any scientific reason.

Representative HOLIFIELD. The word "sunshine" has a cheery note to it, and I was just wondering if we were allowing, let us say, propaganda to creep into our scientific terminology. Why did you not put it "happy" units, or something like that?

Senator ANDERSON. I do think it should be said that he not only did not have anything to do with the naming of it, but never heard of it until he came to these hearings. Was it not the fact that the whole project making this study was given the name "Sunshine Project"?

Mr. TAYLOR. Yes.

Senator ANDERSON. Just as we have "Operation Plumbob" going on. They have put out Project Sunshine as the most enlightened and happiest look on radiation damage.

Mr. TAYLOR. If I might divert just one moment, when I was with the Atomic Energy Commission myself for a year some years ago, we started a problem closely related to this, and we called it "Project Gabriel"—you know, Gabriel blow your horn. That had kind of a sinister sound to it, and it may be that they wanted to undo a little of that.

I think I was about to point out——

Representative HOLIFIELD. I did not know but what maybe this might be a tranquilizing pill.

Mr. TAYLOR. I obviously have had no close connection with this particular project, as you can see.

Getting back to the question of units there has just been published within the last month or so a very complete report on radiation units by the International Commission on Radiological Units, and this I will submit as exhibit 2 of my accompanying material.

With regard to units generally, I might say that at the present time there are standards for all of the basic units. These have been established in various laboratories and are now maintained at the National Bureau of Standards as part of their normal program. However, there are many areas where further research is needed, particularly in the area of absorbed dose.

There are two things needed here. One is some basic development on the standards and instrumentation. This is the type of work that might be done at the Bureau of Standards, or some other comparable laboratory.

I might point out that one of the real difficulties in making progress with this is our inability to get the suitable people to work in a Government laboratory because of the competitive salaries offered by the airplane industry, and so on. This is a real handicap.

There is also a great deal of work needed in clinical and medical institutions, and biological laboratories, on this same question. Work of this sort is going forward, but much more is needed.

On the RBE itself, this, of course, depends upon the absorbed dose studies, and, as I mentioned, there is a great deal of work going on in this area in the Atomic Energy Commission laboratories, as well as others.

Now, in setting of the permissible dose from sources of radiation external to the body, we have to make some basic assumptions. Until 1947, the standards that we used were based almost solely on the effect of the radiation on the individual. In 1947, we began to obtain or have made available to us some more quantitative information on the genetic effects of radiation, and on the effects of radiation on expected life spans (exhibit 3).

At that time, in 1947, while there was this evidence, it was not considered to be sufficiently quantitative to be used in a quantative readjustment of our permissible exposure levels.

In 1952 some tentative levels for the average population dose were set by the International Commission on Radiological Protection, mainly for genetic reasons. The actual promulgation of these recommendations was held up because even then it was felt that the information was not sufficiently quantitative, and there was still time to await better information.

It is rather interesting, in this connection, to notice that the recommendations that were discussed in 1952 are essentially the same as those that were recommended by the International Commission itself in the spring of 1956, and then later by the National Academy of Sciences in its report of last June.

In this connection, I would like to introduce in the record exhibits 4, 5, and 6.

The recommendations of the International Commission, which I will not go into in detail, give 1 or 2 important numbers.

One was that for occupational exposure a person should not receive more than 50 r. e. m. up to age 30, and 50 r. e. m. per decade, or every 10 years thereafter. This is equivalent to an average of about 5 r. e. m. per year. The difficulty, however, is that one cannot work very comfortably to an average that is geared to a yearly accumulation in this way. And particularly for legal purposes there is a great deal of difficulty in interpreting what is meant by a 5 r. e.m. per year average.

Accordingly, the National Committee on Radiation Protection in this country introduced a concept which it hopes will serve to straighten this out somewhat. They have said that the maximum permissible dose for occupational purposes for an individual shall not exceed five times the number of years of age of that person over 18. Eighteen is the age at which persons are allowed to begin radiation work.

You can write that MPD=5 (N–18) rems, where N is his age.

This means that if a person starts to work at age 18, in his first year he can receive 5 rem, and so on.

This material has been described in some detail in quite a number of places. I will introduce one for the record here as exhibit 7. I will return to that in just a moment.

Senator ANDERSON. Does that mean a person has got to be 60 years old to take 42 times 5 rems, or 210 rems?

Mr. TAYLOR. Yes, sir. I have a chart that will show that.

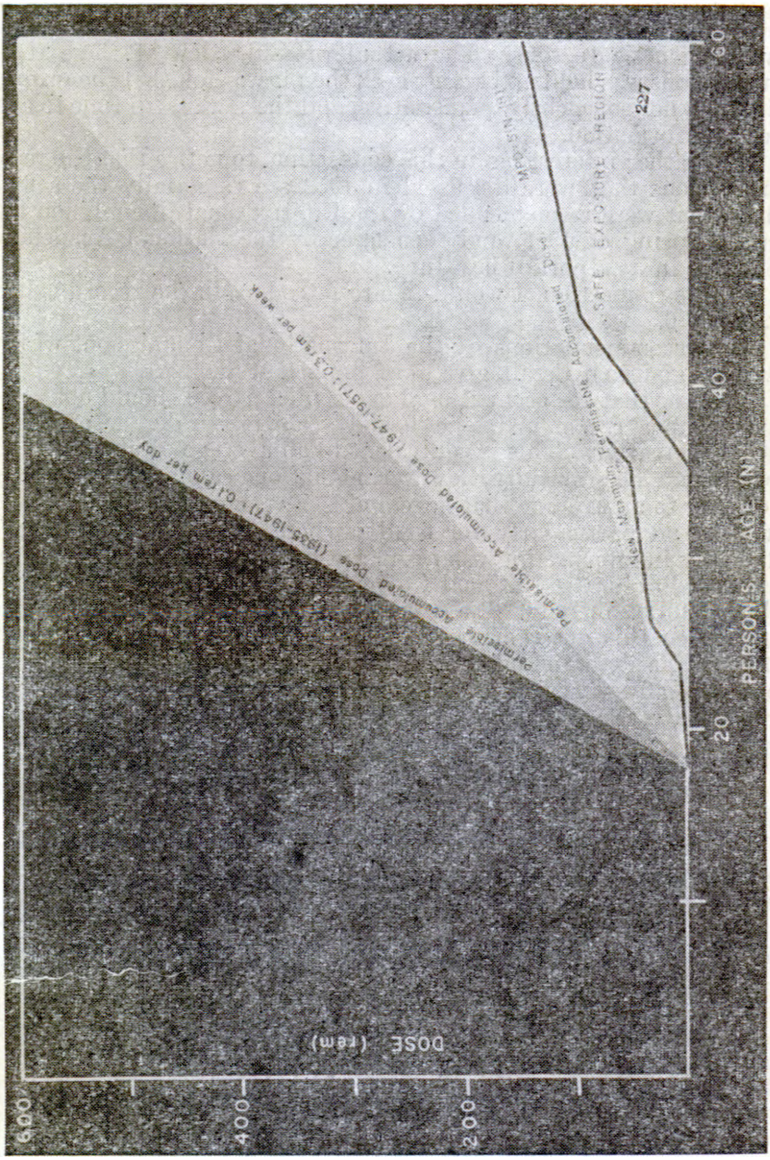
Senator ANDERSON. Is not that a pretty fair sized dose?

Mr. TAYLOR. Yes, but let me show you what is meant by that, if I may, in just one moment.

In connection with this change, which is a lowering of the level we have had up until now, we have still retained tentatively the allowance of 0.3 rem per week, or 15 rem per year, provided that the age-prorated dosages as given by the formula is not exceeded.

I have a chart with me that was prepared for another purpose, but which I think will illustrate the point.

EXHIBIT 1



Permissible Accumulated Dose (1935-1947): 0.1 rem per day
Permissible Accumulated Dose (1947-1957): 0.3 rem per week
New Maximum Permissible Accumulated Dose
SAFE EXPOSURE REGION
227
DOSE (rem)
200
400
600
PERSON'S AGE (N)
20
40
60

Can you see the lower part of it? Do not pay any attention to the upper part.

Here [indicating] we have plotted the dose in rems, 200, 400, 600 rems as a function of the person's age—age 20, 40, and 60.

Now, in the upper region, indicated by this magenta color, is indicated the dose that a person could have received as a function of age under the permissible dose limits that prevailed from the period of 1935 when we had our first dose limits, to 1947, when they were revised.

According to this, a person could receive about 600 rem by age 38. If you extrapolated this up to 60, it would perhaps be twelve or fifteen hundred rem.

Now, 1947——

Representative HOLIFIELD. Who set that particular chart? Who set that? Was that the Radiation Association of Scientists?

Mr. TAYLOR. Well, yes. This particular level of 0.1 rem per day was set in this country by the National Committee on Radiation Protection in 1935 on the basis of the information that we had available to us then. The year before this, in 1934, the International Commission had set a level of 0.2 rem per day which was twice as high as the United States value. This country lowered it to one-tenth of a roentgen per week.

Representative VAN ZANDT. What is the estimated dose count at age 60?

Mr. TAYLOR. It looks like something of the order of maybe 1,200 rem.

Senator ANDERSON. You say this one time there had been a much sharper rise, and therefore a much larger dose indicated prior to 1935?

Mr. TAYLOR. The first permissible dose in quantitative units was set in 1934 by the International Commission of Radiological Protection at two-tenths of a rem per day, and that would have been a curve coming up substantially steeper than the one I have indicated.

Senator ANDERSON. Then this was changed in 1935?

Mr. TAYLOR. This was changed in 1935 by the United States committee.

Senator ANDERSON. And is substantially the same now as it was then?

Mr. TAYLOR: No, sir. I am coming to that.

Senator ANDERSON. You said it had been changed in 1947?

Mr. TAYLOR. Right. In 1947 we began to have, as I mentioned, more information available about genetic effects, longevity effects, and the effects of small doses of radiation. And so in 1947 we lowered the permissible dose from one-tenth rem per day (or six-tenths rem per week), to three-tenths per week. In other words, it was cut in half.

That would have meant, on the basis of the old permissible dose, that at age 60 a person could have received, if he had taken the maximum, something in the order of slightly over 600 rem.

Representative VAN ZANDT. Was that for the 12-year period from 1935 to 1947?

Mr. TAYLOR. Until 1956 or 1957 there was no limitation that was related to age as such. This is a new concept.

Representative VAN ZANDT. What I am trying to develop is why did they make this reduction in dosage?

Mr. TAYLOR. In 1947?

Representative VAN ZANDT. Yes.

Mr. TAYLOR. Prior to Mahattan District days we had very little quantitative evidence to go on. A great deal of biological work was done by the Manhattan District Project in order to protect their own people, and this turned out to be very valuable and useful information with relation to maximum permissible exposures. So it was lowered in 1947 because of better information, because we found that our technological advances would make it possible, and because it just looked like good sense.

Now, in 1956, the International Commission again recommended a further lowering of the dose, and this is represented by the lower part of the graph, the white part on the graph here. This is the dose in relation to age, and according to this, by age 60 a person would be allowed to accumulate approximately 200 roentgens. These are whole body exposures, I am talking about.

Representative HOLIFIELD. That is accumulative?

Mr. TAYLOR. That is accumulated. He can be allowed to accumulate up to approximately 200 roentgens by age 60. This means working from age 18 to 60, or 42 years.

Representative HOLIFIELD. Now you said that you have a new concept of permissible radiation dose in relation to age. Why do you have a difference in the age group? Why do you have a different allowable dose? Does it have to do with the somatic cells and the reproductive cells?

Mr. TAYLOR. It has to do with both the somatic cells and the reproductive cells; yes. Primarily, I would say the reason has to do with the genetic problem. Once you have done this for the genetic problems and introduced the kind of levels necessary for genetic protection, if you speak of it that way, you might just as well continue and provide the improved somatic protection at the older age.

Representative VAN ZANDT. Doctor Taylor, based on experience, have you any figures to indicate the number of people that were actually affected and the number of deaths that resulted from exposures to radiation?

Mr. TAYLOR. Well, I was going to say later, but I might as well say right now, that there is no tangible evidence that I know of, of anybody working under these limits, the 1947 limits, or the new limits, who have been harmed by the radiation levels they were exposed to. In other words, I know of no causative relationship between damage that might develop in an individual, and the radiation to which we were exposed at any of these levels we have been talking about; in fact, even under some of the less conservative levels prior to 1935.

Representative HOLIFIELD. The fact you do not know of any specific cases does not necessarily prove that there has not been damage, and you would not state there has not been damage?

Mr. TAYLOR. I certainly would not. It does, however, indicate the likelihood of damage is quite small. And this is another point that I will come to later. The probability is so small that it requires rather fine statistical techniques, in order to really determine whether there is any effect or not.

Representative HOLIFIELD. But there must be some concern or the scientists would not have been continuously reducing the permissible level there?

Mr. TAYLOR. This is correct. Even back in the early thirties, when we knew very little about this problem, nobody who really thought about the question would say that promiscuous exposure to radiation was harmless. We have always felt it was desirous to limit as far as possible the unnecessary radiation exposure.

Representative HOLIFIELD. I assume we will have a great deal of testimony on this point from other witnesses.

Mr. TAYLOR. I am sure you will; yes.

Senator ANDERSON. I noticed in newspapers of Sunday, May 26, there was a story from Science Service that quoted Dr. W. L. Russell, principal geneticist at the Oak Ridge National Laboratory, in which he said that "Offspring from a man exposed to such radiation will have their lives shortened on the average of 20 days for each unit of the radiation their father has received."

Will you relate that to that chart? Does that mean, going from the 200 level up to the old 600 level, that they would have their lives reduced 400 times 20 days?

Mr. TAYLOR. If his figures are correct.

Senator ANDERSON. I am suggesting we assume the figures are correct. This was from the proceedings of the National Academy of Sciences, and I assume they have given some thought to it.

Mr. TAYLOR. Yes.

Senator ANDERSON. But he said that a man's life would be shortened from 5 to 35 days for each unit of radiation received by his father, and the father's life, of course, would also be shortened. But I am trying to relate it to that chart. Does it mean, going from 200 up to 600, which was the old limit and now brought down to 200—had that been left alone, and assuming Dr. Russell from Oak Ridge and his figures are correct, does that mean their life would be shortened 400 times 20 days?

Mr. TAYLOR. Yes; I think, assuming the figures were correct, this would be what you would expect.

Representative HOLIFIELD. The Chair might say that Dr. Russell will be a witness tomorrow.

Mr. TAYLOR. Right. I would much rather let Dr. Russell discuss this particular question.

Senator ANDERSON. Well, I would like to have you comment on what he said.

Mr. TAYLOR. If the figures are correct—and I am not willing to admit personally that they have been amply proven, although there is a lot of evidence pointing in this direction—then I think you have to accept the sort of life shortening you have just mentioned.

Senator ANDERSON. Something like 20 years, 22 years?

Mr. TAYLOR. What was the figure you gave—20 days per roentgen?

Senator ANDERSON. Twenty days per roentgen. I do not know whether it is per roentgen. It says "each unit of radiation." You were talking about different kinds of units. I do not know whether it refers to rems, curies, sunshine units, or what. I assume it is some kind of a unit.

Mr. TAYLOR. At 20 days per man-rems, you would multiply 20 by 200, and that would be 4,000 days, would it not?

Senator ANDERSON. I am taking the spread from 200, now regarded as safe, up to the 600 they regarded as safe only a few years ago, and

you get 8,000 days or 22 years. Is not that a pretty substantial shortening of life?

Mr. TAYLOR. It is pretty substantial. I do not believe it.

Senator ANDERSON. Well, we are trying to get information here adduced by scientists, and the National Academy of Scientists is a reasonably good body, is it not?

Mr. TAYLOR. I am not in the best position, sir, to discuss that particular point, but I would say this: That I do not believe there is any evidence of a shortening of life span by that many days on the part of people who have been living within these higher permissible exposure levels. If there is such information, I am unaware of it.

Senator ANDERSON. Yes. I was only taking the colors you had in the chart there, and was trying to see what Dr. Russell's statement meant. We will ask him also, but I wondered if it related to your chart. That is all.

Representative HOLIFIELD. Mr. Van Zandt.

Representative VAN ZANDT. To what extend does industry live within these standards of exposure are are they required to live within these limitations?

Mr. TAYLOR. Well, industry has for the last 10 or 12 years been required to live within the limitation covered by the center area down, and by and large they have done this very well. Actually, the Atomic Energy Commission operations have, for safety's sake, been doing better than that, and they have in fact been living within the white area for some considerable time. So that these levels we are talking about now, while they have been reduced by a factor of 3, are probably not going to raise the hackles of the Atomic Energy Commission at all.

Representative VAN ZANDT. It is my understanding when industry is licensed to handle atomic material, they have to then meet the requirements laid down either by the National Bureau of Standards or the Atomic Energy Commission. Is that right?

Mr. TAYLOR. This is correct. And the license requirement calls for living within or below the center region. At some time they may decide to accept the new recommendations and work within the white region.

Representative VAN ZANDT. Do you have any information on the experience of the Navy as far as the *Nautilus* and the *Seawolf* are concerned?

Mr. TAYLOR. As to the exposure of the people?

Representative VAN ZANDT. Yes.

Mr. TAYLOR. I do not have any quantitative information. I will tell you this, though, from personal experience: I made a 24-hour trip on the *Nautilus* about a year ago, and I took onto the ship with me a very sensitive pocket dosimeter, which laid behind the reactor. I could hardly read any radiation, and I should guess that would be the hottest spot, or 1 of the 2 hottest spots on the ship.

Representative VAN ZANDT. Does your experience go back to Arco, Idaho, when the reactor initially went critical?

Mr. TAYLOR. I have no experience with that particular situation, and no knowledge of it.

Representative VAN ZANDT. Then your experience is with the reactor on board the *Nautilus?*

Mr. TAYLOR. Purely a small personal experience.

Representative VAN ZANDT. Do you know of any naval personnel that may have been exposed to a dose beyond the limits that you mention?

Mr. TAYLOR. No, sir; I do not.

I am, understand, getting back to the *Nautilus* for a moment, that you are just about as safe from radiation in the *Nautilus* as you are in the average environment.

Senator ANDERSON. Let me ask you a question. You have me curious now. I went aboard the *Nautilus*, carrying a dosimeter. It registered an increase in radiation. Am I to be regarded as more suspect, as a more rapid carrier?

Mr. TAYLOR. You probably had a hotter wristwatch on than I had. I do not know, sir. As I say, what I did was not done for the purpose of making a quantitive measurement, but just done for a lark.

Representative HOLIFIELD. Of course, it is true they have a full-time doctor on the *Nautilus*, and they have taken every precaution known to science to protect the crew and the people on there from radiation; and this is not to be compared with free radioactive particles that are floating around in the atmosphere.

Mr. TAYLOR. This is quite true. This, of course, also applies to large Commission operations. It is one of the reasons why you allow occupational exposures to be higher than nonoccupational exposures, the individuals who are so exposed, are so well watched over.

Representative HOLIFIELD. You have a continual screening of the air to remove any dust particles in the *Nautilus*, and any solids that might be in the atmosphere, certainly, which gives a purer air to the inhabitants of the *Nautilus* than you would get outside where the free dust is blowing.

Mr. TAYLOR. This is probably correct.

Representative VAN ZANDT. Mr. Chairman?

Representative HOLIFIELD. Mr. Van Zandt.

Representative VAN ZANDT. One more question.

About a week ago, the newspapers carried stories concerning a resident of Texas who had been exposed to radiation, and the stories stated he was completely isolated by not only his fellow employees, but by his neighbors who refused to associate with him. Are you familiar with that situation?

Mr. TAYLOR. No, sir. I know there was some situation down there, but I was away at the time that occurred, and I only know about it secondhand.

Senator BRICKER. Mr. Chairman?

Representative HOLIFIELD. Senator Bricker.

Senator BRICKER. I am a bit mystified as to how you got this 20-day figure or 22-year figure as the shortening of the life period as a result of radiation, since there is no human experimentation possible from which to come to that conclusion. Could it be that you have had animal experimentation from which you deduce that conclusion?

Mr. TAYLOR. You are asking me, sir, questions that I am not in the best position to answer. Dr. Russell is in the room at the present time if you would like to have him answer this.

Representative HOLIFIELD. This is quite complicated, and I think when Dr. Russell comes to the stand, we will go into it in some detail.

Mr. TAYLOR. I think this would be the better way to do it.

Representative HOLIFIELD. I think you had better proceed at this time with your statement.

Mr. TAYLOR. I have talked thus far about occupational exposures to radiation, and I should next point out that for nonoccupational exposure we have set levels that are one-tenth of those for occupational exposure. This was done several years ago for the first time—I think 1953—partly for genetic reasons and partly for somatic reasons. It is also partly a matter of ethics to keep this dose as low as possible, because here you are exposing people where they are in no position to control their own environment.

In connection with these low nonoccupational exposures, it is desirable, when possible, to take advantage of occupancy factors and exposure factors; in other words, the fraction of the time that a person may be exposed or not exposed. There is some evidence that some of these lowered values, these one-tenth values, are going to make for too severe restrictions in certain limited areas, and there is a possibility that they may be slightly raised in the future.

We come, next, to the question of population dose, and here the recommendation has been made that the permissible exposure to the population as a whole should not exceed 14 million man-rems per million of population up to age 30, and one-third of this value per decade thereafter. This value might be changed from 14 million to 15 million, simply to make the arithmetic easier, because we really do not know enough about the problem to know the difference between 14 and 15 anyway.

This means that persons in a population group of, say, a million people can receive an average dose per person of 14 million man-rems, including background radiation. This also implies that some persons may receive subsbtantially more than 14 million man-rems, provided others receive substantially less. This is an average population dose.

I have a chart (exhibit 8, slide 1) that would be of some interest in providing some perspective as to the sources of radiation with which we are dealing these days.

This is a chart that indicates in a very rough way the dose distribution in the population for people up to age 30.

Of this, the background will provide a dose of about 4 million man-rems per million of population.

Representative HOLIFIELD. Is that the natural background?

Mr. TAYLOR. That is the natural background; yes, sir.

There is slight uncertainty in all of these figures, but that is close enough. This, of course, applies to a hundred percent of the population.

Then we have from medical usage, exposures which have been estimated at somewhere between 1 and 5 million man-rems per million population. The figure 1 is the European figure, and the figure 5 is the American figure, and I suspect that the true figure, if it is ever found, will be somewhere between the two.

Representative VAN ZANDT. Is that where you use radiation for medical purposes?

Mr. TAYLOR. That is correct. This you think of as applying to 100 percent of the million people we are talking about. Actually some will get no radiation, and others will get more.

Representative VAN ZANDT. Dr. Taylor, is that the amount that the individual will be allowed until he reaches 30 years of age; is that correct?

Mr. TAYLOR. This is what they are getting now, as far as we can judge from present practices.

Representative VAN ZANDT. Spread over a period of 30 years?

Mr. TAYLOR. Yes.

Representative VAN ZANDT. Suppose they take the dose all at once.

Mr. TAYLOR. Within reasonable limits, this might be all right. There may be extreme cases where it would not be all right.

The total allowable amount we are going to talk about is this 14 million man-rems per million population.

Now, our occupational exposure at the new levels of 5 man-rems per year average would put into the population 150,000 man-rems as compared with 4 million and 5 million man-rems from medical exposure. This, however, as you see, applies only to a third of 1 percent of the population, which is an estimate that we think is reasonable for some years to come.

Then we allow in the environs of a plant, one-tenth of the occupational levels, and that would contribute another 150,000 man-rems to the population dose. And we have just made a guesstimate that that might apply to 1 percent of the population. To give you some idea of the reasonableness of this estimate, that would be something of the order of 16 million people living in the immediate environs of radiation sources, which I suspect is a very high figure for today.

Finally, we have last, "Fallout" for which I have allotted 200,000 man-rems per million of population. I think the National Academy figure here would have come to 100,000. Other estimates have been higher, but still you see it is quite small.

If you total these up, the things we know about, and the fair guesses, this comes to about 9½ million man-rems. This means that if you allow 14 million total that we have a balance of about 4 million man-rems that can be used up in other ways. Some of this will be used up in radioactive devices in the homes. You might use some of this in medical exposure, you might use some of this in fallout, and so on. But there is still a little room for motion here, as far as our uses of radiation are concerned.

Representative VAN ZANDT. Dr. Taylor, are these figures based on the radiation in the atmosphere today plus what will be in the atmosphere, say 5, 10, or 15 years from now?

Mr. TAYLOR. No, sir. These are based on the situation today.

Representative VAN ZANDT. Today?

Mr. TAYLOR. Right. Yes.

I am sorry. I skipped one point in connection with this previous discussion which I would like to return to, if I may, for just a moment. This has to do with working within the white region under our new levels.

So long as a person's dose accumulates at such a rate that he never exceeds the line at the top of the white area, he can acquire his dose at varying rates. If he starts work late in life, say at age 35, he can accept his dose at the rate of 15 man-rems per year, until he begins

to get up close to the top, at which time prudence would say he should taper off a bit. This is one of the nice features about this concept, because it gives the plant enormous latitudes in designing their safety operations. This is discussed in item 7 of the exhibit material.

Representative HOLIFIELD. You will submit both charts for the record, will you not?

Mr. TAYLOR. Yes, sir; and with reference to the other chart I showed, I would refer you to item 8 of the material.

Now, these standards that I have been talking about apply to the whole body, the lens of the eyes, and the gonads. They apply to all kinds of radiation, but obviously we need a great deal more information than we now have with regard to the RBE for the different radiations, and for the different organs.

Representative VAN ZANDT. May I ask a question at this point?

Mr. TAYLOR. Yes, sir.

Representative VAN ZANDT. Mr. Taylor, suppose an individual takes the limit of the dose up to the age of 30, then he leaves the industry, and comes back at age 50, and starts all over again. What has happened to the dose he took prior to and up to the time he was 30 years of age?

Mr. TAYLOR. There would probably have been some recovery from that dose, but for control purposes, you will assume there has been no recovery.

Representative VAN ZANDT. In other words, you assume that some radiation is still in his body?

Mr. TAYLOR. That is what you would assume. He would then between age 30 and 50 have been out of radiation work for 20 years. For each of those 20 years, he would have built up an allowance of 5 man-rems, or a hundred man-rems total. He can then take 15 man-rems per year until he begins to get up close to that, and then he would begin to flatten off again.

Representative HOLIFIELD. Doctor, we are going to have to move along. We are running a little behind schedule, and we have two other witnesses this morning. Are you in a position now to begin your summary?

Mr. TAYLOR. Well, I can do that.

Representative HOLIFIELD. How many more items had you planned on discussing?

Mr. TAYLOR. There were several. There has been a lot of side discussion I had not counted on.

Representative HOLIFIELD. I know there has. It is not your fault. Go ahead.

Mr. TAYLOR. I will touch very quickly on some of these points.

Representative HOLIFIELD. I understand you are going to submit for the record a complete treatment of each one of these subjects.

Mr. TAYLOR. This is correct; yes.

In dealing with the exposure of the body to different kinds of radiation, whether it be external sources of radiation or internal sources of radiation, you would have to treat each source and each body organ separately, the dose to those organs, the RBE for that dose, and so on. This again is an extremely complicated problem, and

one about which we have relatively little quantitative knowledge at the present time.

The new recommendations that I have been referring to and that will make for a lowering of the accumulated dose will not apply in this same way to internal emitters. Most of the permissible dose levels for internal emitters will remain at the values that they are currently. This is because only partial body exposure is involved, and, therefore, you do not need to go into the same extensive lowering of internal dose that you do for external dose.

This, incidentally, is going to somewhat simplify, or at least not make more complicated the atomic energy operations as they are now being carried out.

With relation to strontium 90, the permissible dose of strontium 90 in the body is related to the knowledge that we have of the effects of radium in the body, and primarily in the bone. You cannot compare these exactly because radium is an alpha emitter, and strontium is a beta emitter. In the process of arriving at a permissible dose for strontium various factors of uncertainty have been resolved in such a way that I believe I am correct in saying the permissible levels for strontium may be as much as 15 times more conservative than the levels we have for other radioactive isotopes. This will undoubtedly be discussed by one of the later speakers.

Without going into any discussion, I will introduce into the record discussion of the various international and national committee activties by introducing items 9 through 15 of the supporting material.

In connection with the question of permissible dose standards, there are, as I have indicated, a large number of variables, and a large number of uncertainties. We do not have now, and probably will not have for a long time, any quantitative evaluation of the risks involved. What somebody has to do, is to evaluate the risk due to radiation against the benefits from the use of radiation, and the risk due to other things that affect our normal life.

In this connection I frequently feel compelled to say that this question of radiation safety and permissible dosage standards is not a subject for which there is a clean and simple answer. The whole question of setting radiation exposure limits depends on physics and biology. It depends enormously on ethics and morality, and on an enormous amount good judgment and good wisdom on the part of the people who are responsible for setting them. It is by no means a clean-cut quantitative physical problem.

I was asked specifically to comment on the possible effects of the use of different protection standards by different nations, as to whether this might introduce some kind of misunderstanding between nations. This is fortunately an academic question at the present time.

In this country, the States and the Federal Government use the recommendations of the National Committee on Radiation Protection. As far as I am aware, all countries in the world, including the Iron Curtain countries, use the recommendations of the International Commission on Radiological Protection. These are in exact agreement with those that are used in this country. Perhaps they could not help but be because of the close relationship between the United States national and the international committees.

A problem does exist, at the present time, with regard to both national and international bodies working on these questions. This problem had to do with the plethora of organizations that are setting up various kinds of protection groups and protection studies. The manpower that is knowledgeable in this area is very limited, and the same people are called on repeatedly, wearing different hats, to engage in different and overlapping activities. To avoid this, the international commissions are presently setting up formal working relationships with various other international organizations—WHO, ILO, UNESCO, ISO, and so on—about a dozen organizations. These have their own special interests, but by common consent they now look to the two international commissions for their basic guidance.

One of the big question marks in the future is whether the new International Atomic Energy Agency will do this also. It is to be hoped that they will.

I think at this point, sir, I will stop. I have gone way over the time that was originally allotted me.

Representative HOLIFIELD. I am sure that your presentation has been very valuable to us, and I know that the documentation which you told me of previous to the meeting will be additionally valuable. You did take up in this documentation the comparison of strontium 90, the 100 permissible dose as against the 1,000?

Mr. TAYLOR. The sunshine unit?

Representative HOLIFIELD. Yes.

Mr. TAYLOR. No, sir; that is not in my documents. I have no documents on that, but I am sure that will be documented from other sources in the course of the hearing.

Representative HOLIFIELD. Thank you very much, Mr. Taylor.

(Mr. Taylor's full statement with exhibits follows:)

STATEMENT OF DR. LAURISTON S. TAYLOR, CHIEF, ATOMIC AND RADIATION PHYSICS DIVISION, NATIONAL BUREAU OF STANDARDS

The main purpose of this part of the discussion before your committee is to give some background in the matter of radiation protection standards, and to indicate areas of uncertainty and reasonable certainty in this field. Mention will also be made of some specific areas of research that should have more emphasis.

RADIATION UNITS AND STANDARDS

Until about 1928 any protective measures that we had were on an almost purely guess-work basis because of lack of radiation units and standards. The adoption of the roentgen in 1928 was the first step leading to the first quantitative radiation protection standards 6 years later. The roentgen was the only radiation unit until the early 1930's and applied only to X- and gamma-rays. Of course until the early forties' we had essentially no other radiations to worry about. The roentgen is still an important and useful unit of exposure dose within its limitations.

Recognizing the need for a universal unit of dose, the International Commission on Radiological Units and Measurements, in 1953, adopted the rad, a unit of absorbed dose that applies to all radiations. The rad measures the energy imparted to matter by the ionizing particles, per unit mass of irradiated material at the place of interest, and is equal to 100 ergs per gram. However, it is still difficult to measure a rad directly and on this much more developmental research is needed.

Dose rate is a commonly used term. As its name implies it is the rate of administering a dose. In many radiation effects the rate of administering the dose can have an important influence on the ultimate biological effect. It

may be compared with a dose of aspirin. You might say that one tablet was one dose, or that eight tablets was one dose. In the latter case it makes a great deal of difference whether the prescription says to take the eight tablets all at once, or eight per hour, or eight per day. The results upon the individual might be quite different under the various circumstances just noted.

The rep is a unit that has been mentioned several times in previous testimony. This unit was invented during the early Manhattan District days for equating various radiation effects of different kinds of radiation. One of the difficulties with the rep at present is the fact that it has been redefined at various times with the result that one is never exactly sure as to what is meant by the term. In view of present-day knowledge it is certainly not 93 ergs per gram as mentioned by one of the earlier speakers. It is our hope that the use of the rep will be completely discontinued.

The RBE, standing for relative biological effectiveness, is a very important term, and is used in equating the biological effects of various kinds of radiation, such as alpha, beta, gamma, and X-rays, neutrons, etc. All values of RBE are related to an assumed value of RBE=1 for X-rays of the energy more commonly used therapeutically. The RBE depends upon many factors, such as the kind of radiation, body organ, kind of effect caused, absorbed dose, absorbed dose-rate, dose fractionation, pH, oxygen tension, temperature, etc. Because of its dependence on all of these factors, it is not too surprising that our present-day knowledge of RBE values is not all that it should be. For alpha particles, the RBE may vary between 2 and 10, depending upon the interpretation of various experiments.

At the present time the RBE is known only roughly in many important areas and much more research is needed in the study of this factor. The National Committee on Radiation Protection (NCRP) has a subcommittee working actively on this whole question under the direction of Dr. Wright Langham of Los Alamos. At present the subcommittee is compiling and correlating a vast amount of data and are developing specific areas where further research is needed. It should be pointed out that our lack of knowledge of the RBE is probably not introducing a danger factor in the setting of our permissible dose levels. We can make some reasonable estimates of the upper and lower limits of the RBE for particular circumstances, and where there is any uncertainty a higher or more conservative value is chosen. On the other hand, use of too high values for the RBE can cause us to be over-protecting ourselves, at some considerable cost.

Another radiation unit is the rem, a unit of RBE dose, which essentially includes all of the factors entering into the biological dose as well as they may be known. An RBE dose expressed in rems is equal to the product of the absorbed dose in rads and the RBE. Thus, RBE dose in rem=Σ[absorbed dose (rads) x RBE].

The Curie is not a unit of dose but a unit of an amount of radioactive material. It is related to the number of disintegrations that occur per second in radioactive material and this, in turn, specifies the amount. It may be compared with a unit of mass and, in fact, one curie is equivalent to 1 gram of radium

Another unit used in connection with Sr–90 problems is known as the "sunshine unit." This is related to the maximum permissible average body burden of Sr–90 in the population outside of controlled areas. One sunshine unit is equal to one-hundredth of the average permissible body burden for the general population. If one considers that the maximum permissible body burden for radiation workers is one micro-curie of Sr–90, then the permissible body burden for persons outside of controlled areas would be 0.1 microcuri of Sr–90. Since the body contains about 1,000 grams of calcium this body burden would amount to 0.1 microcuries of Sr–90 per thousand grams of calcium. This reduces to 100 $\mu\mu$curies of Sr–90 per gram of calcium. One sunshine unit is one-hundredth of this quantity.

STATUS OF UNITS

On the whole it is considered that our situation with regard to radiation units is fairly well in hand, as exemplified by the latest report of the International Commission on Radiological Units and Measurements in 1957.

Exhibit 2. National Bureau of Standards Handbook 62, Report of the International Commission on Radiological Units and Measurements (ICRU) Pages 5–7, 1956

I. Quantities, Units, and Symbols

1. DEFINITIONS OF QUANTITIES AND UNITS [1]

1.1.[2] Absorbed dose of any ionizing radiation is the energy imparted to matter by ionizing particles per unit mass of irradiated material at the place of interest.

1.2. The unit of absorbed dose is the rad. 1 rad is 100 ergs/g.

1.3. Integral absorbed dose in a certain region is the energy imparted to matter by ionizing particles in that region.

1.4. The unit of integral absorbed dose is the gram rad. 1 gram rad is 100 ergs.

1.5.[2] Absorbed dose rate is the absorbed dose per unit time.

1.6. The unit of absorbed dose rate is the rad per unit time.

1.7. Exposure dose of X- or gamma radiation at a certain place is a measure of the radiation that is based upon its ability to produce ionization.

1.8. The unit of exposure dose of X- or gamma radiation is the roentgen (r). One roentgen is an exposure dose of X- or gamma radiation such that the associated corpuscular emission per 0.001293 g of air produces, in air, ions carrying 1 electrostatic unit of quantity of electricity of either sign.

1.9. Exposure dose rate is the exposure dose per unit time.

1.10. The unit of exposure dose rate is the roentgen per unit time.

1.11. Intensity of radiation (radiant energy flux density) at a given place is the energy per unit time entering a small sphere of unit cross-sectional area centered at that place.

1.12. The unit of intensity of radiation may be erg per square centimeter second, or watt per square centimeter.

1.13. The unit of quantity of radioactive material, evaluated according to its radioactivity, is the curie (c). One curie is a quantity of a radioactive nuclide in which the number of disintegrations per second is 3.700×10^{10}.

1.14. Specific gamma-ray emission (specific gamma-ray output) of a radioactive nuclide is the exposure dose rate produced by the unfiltered gamma rays from a point source of a defined quantity of that nuclide at a defined distance.

1.15. The unit of specific gamma-ray emission is the roentgen per millicurie hour (r/mch) at 1 cm.

1.16. Linear energy transfer (LET) is the linear-rate of loss of energy (locally absorbed) by an ionizing particle traversing a material medium.

1.17. Linear energy transfer may be conveniently expressed in kilo electron volts per micron (kev/μ).

1.18. Mass stopping power is the loss of energy per unit mass per unit area by an ionizing particle traversing a material medium.

1.19. Mass stopping power may be conveniently expressed in kilo electron volts per milligram per square centimeter (kev cm^2/mg).

Notes on the following definitions

The numbering corresponds to the paragraphs above.

1.1 Absorbed dose.

(a) In the definition of absorbed dose "energy imparted to matter" means energy retained by matter and made locally available at the place of interest. The absorbed dose includes all energy absorbed per gram of any material under consideration. Thus it includes the energy of nuclear collisions as well as that of electronic collisions.

---

[1] Symbols and nomenclature. There are numerous national and international bodies that have reached varying degrees of acceptance of the use of symbols and units for physical quantities. However, there is no universal acceptance of any one set of recommendations. It is suggested that each country modify the symbols used herein, in accordance with its own practices. Thus one may write: kev, keV, or Kev; ^{14}C or C^{14}; rad per unit time, rad per time, or rad divided by time; rad/sec, rad/s, or rad's^{-7}; etc. The most generally accepted system of symbols and units may be that contained in Document UIP 6 (1955) prepared by the International Union of Pure and Applied Physics. These are in fairly close agreement with the recommendations of the International Standardization Organization project ISO/TC 12, the Conférence Générale de Poids et Mesures, Union Internationale de Chimie Pure et Appliquée, and the International Electrotechnical Committee. No effort is being made in the present report to conform to the standards recommended by the above organizations.

[2] See notes following these definitions.

(b) Because the rad does not specify the medium, the medium should be stated unless it is clearly implied. For example it is convenient to use the term "tissue rad," which corresponds to a rad at the point of interest in soft human tissue.

(c) Absorbed dose may be estimated by application of the cavity relation whereby the energy imparted to a solid per unit mass, $(\Delta E/\Delta m)=E_m$, is related to the ionization per unit mass of gas, $(\Delta J/\Delta m)=J_m$, by the equation

$$E_m=J_m W s_m, \qquad (1)$$

where s_m is the ratio of the mass stopping power of the material to that of the gas.

(d) Whenever ionization methods are used for the estimation of absorbed dose, the observed ionization must be multiplied by a quantity W equal to the average energy expended by ionizing particles in the production of an ion pair in the gas.

The value of W for X- and gamma radiation probably lies between 33 and 35 ev for air. It is recommended that the value of $W=34$ ev be used for calculations involving X- and gamma radiation of quantum energy greater than 20 kev. Section 5 contains the currently recommended values of W and s_m as needed in X- and gamma radiation and neutron dosimetry.

1.5 Absorbed dose rate.

It should be pointed out that there are special situations when the absorbed dose rate should be expressed more explicitly. For example: when the absorbed dose rate is not constant during the time of irradiation, it may be desirable to specify also the instantaneous absorbed dose rate. It is recognized that the term "instantaneous" may not always be sufficiently explicit and that perhaps a statement should be added referring specifically to an absorbed does rate of pulsed radiation averaged over a single pulse.

1.7 Exposure dose of X- or gamma radiation.

(a) The translation of "exposure dose" into German is "Bestrahlungsdosis," into French "dose d'exposition," and into Spanish "dosis de exposición."

(b) Although the definition of exposure dose was purposely stated in loose terms, a more physically specific definition might be as follows: "the exposure dose is measured by the ion charge, ΔQ, of either sign, produced in air by the secondary electrons, which are produced by X- or gamma radiation in a small mass, Δm, of air divided by Δm." Note that according to the above definition, ΔQ is *not* the charge measured in Δm. However, under electronic equilibrium conditions, the charge produced in Δm is numerically equal to ΔQ (see sections 1.8 (a), 4.2.a, and 5.2).

(c) The wording of this definition leaves open the possibility of later defining exposure dose for radiations other than X- or gamma rays.

1.8. The roentgen.

(a) According to the definition, a dose of one roentgen is obtained at a point if the high-speed electrons generated in 0.001293 g of dry air at that point produce along their track 1 esu of ions of either sign. Accurate measurements in roentgens are not obtained by actually measuring these ions. Instead the concept of electronic equilibrium is used so that one can measure the ionization per 0.001293 g of air. According to this concept the ionization produced outside of a small mass, m, by high-speed electrons generated inside of m is compensated by ionization produced inside m by electrons generated outside of m (Fano, 1954).

(b) The corpuscular emission shall not include contributions due to secondary X- or gamma radiation produced in the quantity of air in which the corpuscular (electron) emission referred to is generated. This follows from a consideration of the actual definition of the roentgen and the concept of electronic equilibrium.

(c) It becomes increasingly difficult (because of electronic equilibrium limitations) to determine the exposure dose in roentgens as the quantum energy of the X- or gamma radiation approaches very high values. For practical purposes, 3 Mev is arbitrarily regarded as the useful upper limit of the energy range over which the roentgen should be used.

1.9. Exposure dose rate.

(a) Exposure dose rate can be used to specify a field of irradiation or the output from an X- or gamma-radiation source up to 3 Mev.

(b) For quantum energies above 3 Mev, the ICRU at present is not in a position to make a firm recommendation on the specification of output from a radiation source. One may use either intensity, or the absorbed dose rate at

the peak of the buildup curve in a phantom under specified conditions; the latter may be derived from ionization measurements.

(c) It should be pointed out that there are special situations when the exposure dose rate should be expressed more explicitly. For example, when the exposure dose rate is not constant during the time of irradiation, it may be desirable to specify also the instantaneous exposure dose rate. It is recognized that the term "instantaneous" may not always be sufficiently explicit and that perhaps a statement should be added referring specifically to an exposure dose rate of pulsed radiation averaged over a single pulse.

2. RECOGNIZED SYMBOLS

2.1 RBE (relative biological effectiveness). RBE is used to compare the effectiveness of absorbed dose of radiation delivered in different ways. It has been commonly represented by the symbol η. It signifies that m rads delivered by a particular irradiation procedure produces a biological response identical with that produced by $m\eta$ rads delivered by a different procedure.

The statement that "the RBE of α radiation relative to γ radiation is 10" signifies that m rads of α radiation produces a particular biological response in the same degree as $10m$ rads of γ radiation. This statement may be further summarized as $\eta\frac{\alpha}{\gamma}=10$.

The concept of RBE has a limited usefulness because the biological effectiveness of any radiation depends on many factors. Thus the RBE of two radiations cannot in general be expressed by a single factor but varies with many subsidiary factors, such as the type and degree of biological damage (and hence with the absorbed dose), the absorbed dose rate, the fractionation, the oxygen tension, the pH, and the temperature.

2.2. RBE dose is equal numerically to the product of the dose in rads and an agreed conventional value of the RBE with respect to a particular form of radiation effect. The standard of comparison is X- or gamma radiation having a LET in water of 3 kev/μ delivered at a rate of about 10 rad/min.

2.3. The unit of RBE dose is the rem. It has the same adherent looseness as the RBE and in addition assumes conventional and not necessarily measured values of RBE. It is therefore recommended that its use be restricted to statements relating to radiation protection. For example, the statement might be made:

> The permissible weekly whole body RBE dose is 0.3 rem regardless of the type of radiation to which a person is exposed.

Should occasion arise when results have been evaluated with other than agreed conventional values of RBE, the values used should be clearly stated.

In the case of mixed radiations the RBE dose is assumed to be equal to the sum of the products of the absorbed dose of each radiation and its RBE:

RBE dose in rems=Σ[(absorbed dose in rads)$\times$RBE].

(Mr. Taylor's statement—continued.)

Standards of all of the basic physical units have been established and are maintained at the National Bureau of Standrds. However, further research is needed in certain areas.

More research and development is needed on the units and standards of absorbed dose (rad). The physical aspect of this problem should be carried out at the National Bureau of Standards, but here there is a severe difficulty, through the inability to secure properly qualified personnel at salaries that can be paid by the Government. In addition to this, considerable research on clinical applications of the absorbed dose concept should be developed in medical and biological institutions.

As noted above more research is needed on the RBE. This, in turn, depends upon the studies of absorbed dose and absorbed dose standards. The biological aspects of this work are already being carried out by the Atomic Energy Commission and various biomedical groups, but more effort is need.

STANDARDS OF PERMISSIBLE DOSE FROM SOURCES OF RADIATION EXTERNAL TO THE BODY

Until 1947 standards of permissible dose were based almost solely upon the radiation effects on the individual. There was an awareness that this might not

be sufficient but as already noted quantitative evidence and other effects was lacking. In 1947 considerable new evidence had been developed, as a result of studies in the Manhattan District project. These gave strong indications that genetic and longevity effects should be considered but again lack of a sufficient evidence at that time prevented their quantitative use. The effects, if any, were either marginal or were of such a long-range value that their true assessment could be attained only by critical statistical analysis. At the time we were not yet ready to go forward with this.

EXHIBIT 3. NATIONAL BUREAU OF STANDARDS HANDBOOK 50, PERMISSIBLE DOSE FROM EXTERNAL SOURCES OF IONIZING RADIATION, SECTION 3.9 AND 3.10, PAGES 17–20, SEPTEMBER 1954

3.9. GENETIC EFFECTS

Ionizing radiations are capable of producing changes in indivdual genes and chromosomes in all nucleated body cells. The subsequent manifestations of these primary effects (when sufficiently marked) are generally deleterious to the individual in his lifetime and to future generations when they occur in the germ cells. It has been shown experimentally that genetic changes can be produced with low doses of radiation. The frequency of occurrence increases linearly with the dose in the case of gene mutations and is independent of the duration of the exposure. In the case of chromosome breaks with subsequent abnormal union of some fragments (e. g., translocation) the frequency of occurrence depends also on the dosage rate, within certain limits. It is evident that wheher an individual is particularly susceptible or not, some injury of this type is unavoidable. Some cells in his body, including some germ cells, will be genetically altered. However, *genetic changes of the same kind occur spontaneously* and one is not dealing with a mysterious injury of an entirely new type. The main point is to control exposure in such a way that the eventual manifestation of genetic injury is not too large in comparison with the occurrence of spontaneous genetic abnormalities. Insofar as the welfare of the race is concerned (i. e., future generations) gene mutations with inconspicuous manifestations play the most important part. The controlling factor is then the number of undesirable genes (both spontaneous and radiation-induced ones) present in the general population in which intermarriage occurs. It is, therefore, immaterial in this case whether in one generation the undesirable genes are present largely in a few individuals or are distributed throughout the population in correspondingly smaller number per individual. Accordingly, the amount of radiation received by the gonads of one individual up to the time of conception of the last child in his family, can be very large without noticeably damaging the population as a whole—provided that only a very small fraction of the whole population is exposed to this extent. Under present conditions and for some time to come, genetic damage to the population as a whole in future generations is not a limiting factor in setting up a permissible level for occupational exposure to ionizing radiation. For other reasons the level must be considerably lower than might be set on the above grounds. However, it is well to bear in mind that this factor assumes greater importance as the percentage of the population exposed to radiation increases. Moreover, it should be realized that any amount of radiation received by the gonads of even a few individuals before the end of their reproductive period is likely to add to the number of undesirable genes present in the population. While the majority of these genes may have no recognizable effects for a number of generations, practically all are potentially bound to result eventually in undesirable conditions.

Considering now genetic damage manifestable in the lifetime of the individual or in the first-generation offspring, it is obviously necessary to limit the exposure of *every* individual. Chromosomal damage in somatic cells may be responsible, at least in part, for radiation injuries that become evident in the lifetime of the exposed individual. Very little is known about this (which in essence has to do with the mechanism of the action of radiation), but a great deal is known about the observable effects themselves. For purposes of protection it is sufficient to choose a level of exposure that will effectively prevent the occurrence of the injurious effects no matter how they are produced. Genetic changes manifestable in the first-generation offspring are of concern to the exposed individual, since his well-being depends in no small degree on psychological factors in his family life. Sterility, stillbirths, and abnormal children may be produced by overexposure of radiation. Most of the information on these effects has been obtained from animal experiments, but it may be taken for granted that the same effects

occur in man. However, practical experience indicates that undesirable effects of this nature, if present, have not been so marked as to attract attention, in the case of radiologists and technicians who have been occupationally exposed to radiation—sometimes excessively, as shown by other more obvious injuries. It should be noted in this connection that sterility, stillbirths, and abnormal children occur in nature spontaneously or for reasons in which exposure to radiation plays no part. In any particular instance, it is therefore extremely difficult to attribute any such effect to radiation.

3.10. EFFECT ON LIFESPAN

Experiments performed with laboratory animals (chiefly mice and rats) show that exposure to radiation *in sufficient amounts* shortens the average lifespan. This has been found to be true under a variety of different conditions of irradiation, including daily exposures and single treatments. In all these experiments survival curves of the irradiated animals are compared with survival curves of a control group. Because there is always considerable biological variability, small differences in survival curves may occur in the control groups themselves. Hence small differences caused by exposure to radiation are obscured and cannot be considered significant. In order to establish small differences it is necessary to use very large numbers of animals (of the order of thousands rather than dozens) and to take many precautions. Because the number of animals used in such experiments has been too small, it has been customary to extrapolate to smaller doses the results obtained with doses so large that significant differences could be established. Following this procedure it may be shown that an appreciable shortening of the lifespan occurs in mice and rats exposed daily to doses of X-rays in the neighborhood of 0.1 r. Whether this extrapolation is justified or not cannot be decided at the present time. Experimental data on lifespan obtained with other laboratory animals are quite fragmentary and extrapolation to low daily doses is even more uncertain. No quantitative information is available in the case of man. Because the possibility of a shortening of the lifespan in man by small daily doses cannot be excluded, the available experimental data may be assumed to indicate the desirability of lowering the permissible daily dose for lifetime exposure of the whole body to penetrating radiation.

Essentially the same situation exists in connection with the interpretation of other gross effects produced by continued exposure of the whole body to penetrating radiation. Small effects are difficult to determine accurately unless very large numbers of experimental and control animals are used.

(Mr. Taylor's statement—continued.)

In 1952 the International Commission on Radiological Protection arrived at tentative agreement regarding an average population dose that would take into consideration the genetics hazard. However, actual promulgation of any recommendations were held up because it was not considered that the urgency was very great and that, in fact, it would be wiser to await better information. It is interesting to note that the tentative agreements of 1952 were in close accord wih those later recommended by the ICRP in April 1956 and later by the National Academy of Sciences in the same year.

EXHIBIT 4. NATIONAL BUREAU OF STANDARDS TECHNICAL NEWS BULLETIN, MEETINGS ON RADIATION UNITS AND PROTECTION, VOLUME 40, NO. 7, JULY 1956

MEETINGS ON RADIATION UNITS AND PROTECTION

Important decisions relating to the measurement and safe use of radiations were announced at the triennial meetings of the International Commission on Radiological Units and the International Commission on Radiological Protection, both of which were held April 2–11, 1956, in Geneva, Switzerland.[1] In a move to achieve greater international uniformity of X-ray measurements, the ICRU initiated a project in which basic equipment, to be developed by the Bureau, will be loaned to countries that lack primary standards of their own. The principal outcome of ICRP deliberations, on the other hand, was a revised set

[1] The reports of the two commissions are expected to be published in the late fall of 1956. The ICRU report will appear in the form of an NBS Handbook and the ICRP report will be published as a supplement to the British Journal of Radiology.

of recommendations for permissible levels of ionizing radiation to which human beings may be exposed. Another highlight of the ICRU meetings was a discussion of problems raised in translating measurements made in roentgens to the newer unit of absorbed dose, the *rad.*

UNITS COMMISSION

The ICRU has been in active existence since it was established by the first International Congress of Radiology in 1925. Its major objective is the establishment of units of radiation dosage for use in medicine and biology, and in this field it has set the world pattern for over 30 years. At the same time, it deals with special problems of radiation measurement in both clinical and biological applications, and establishes the necessary nomenclature and descriptive procedures in regard to radiation doses.

Problems facing the ICRU have become increasingly complex as radiation energies have moved to higher and higher values, and as other ionizing radiations requiring measurement, such as neutrons, have been introduced. An important step in advancing the common base for all radiation measurements was taken in 1953 with the introduction of an energy unit of measurement called the *rad.* The rad, equal to 100 ergs per gram of irradiated matter, for the first time expresses radiation dose directly in terms of basic physical units. Determination of dose in terms of the older unit, the roentgen, involves only ionization measurements, and the transition to the technique of energy measurement has been difficult. Much of the recent meeting was therefore devoted to developing background material needed to make energy measurements more practical under clinical and experimental conditions. The forthcoming report of the Commission will contain not only this extensive body of material, but also the physical and numerical factors needed to convert ionization measurements made with conventional instruments to energy measurements applicable to radiation absorption in tissue.

It was brought out at the ICRU meeting that few countries have primary standards of X-ray dosage with the requisite range and accuracy. Though in the recent or distant past, intercomparisons of primary standards have been made between the United States, Great Britain, Sweden, France, Germany, and Canada, a great many other countries that use X-rays and gamma rays from radioactive nuclides are without the benefits of central national laboratories. To improve this situation, the Commission recommended that a secondary X-ray standard be developed and constructed which can be loaned to other countries for the calibration of the working standards which in turn are used to control radiation measurements in their hospitals and research institutions.

The National Bureau of Standards was asked to undertake this program and has agreed to do so. The plan is for the Bureau to construct a suitable cavity ionization chamber which can be calibrated over a wide energy range against the NBS primary standards. To control the measurements of the ionization chamber, a standard capacitor will also be provided. The Bureau will also supply a standard diaphragm to be used in intercomparing free-air standards in those laboratories having them.

PROTECTION COMMISSION

Established in 1928, the ICRP has had the responsibility for setting the working levels of ionization radiation to which all persons may safely be exposed. When the Commission's work began, there was little thought that its findings and recommendations would play so important a part in the international picture of radiation use. It was fortunate, indeed, that its first recommendations on permissible exposure, made in 1934, were able to provide the guidelines for protection.

Work of the ICRP has been closely paralleled by that of the United States National Committee on Radiation Protection (NCRP), which was formed in 1929. The two groups have substantial overlapping of membership on their subcommittees which, in turn, are formed along similar lines. In fact, a part of the present international recommendations on radiological protection follows the pattern set by the NCRP.

The 1934 recommendations on permissible exposures were based mainly on the possible harm to the individual working with X-rays. Virtually no thought was given to possible genetic effects. However, as a result of the intensified study of this question during the Manhattan district days, and new evidence which indi-

cated the possibility of both genetic effects and long-range effects on the individual, a review of these questions was made by both the national and international commissions. In 1948, the NCRP recommended that the permissible levels of radiation exposure be reduced by a factor of about two. Thus the permissible exposure of 0.1 roentgen per day was lowered to 0.3 roentgen per week. The same basic figure was subsequently adopted by the ICRP in 1950.

Since 1950 it has become increasingly clear that larger fractions of the population will be exposed to radiation from both medical and atomic-energy sources. It therefore, became paramount to reassess the whole protection problem, and to take into account the newer evidence on possible long-range genetic effects and possible shortening of individual lifespan due to radiation exposure. The ICRP took up these problems at Stockholm in 1952, and its latest recommendations again provide for a lowering of the permissible exposure.

It is proposed that a lowering be achieved without changing the basic level of 0.3 roentgen per week. If this maximum level were maintained indefinitely, it would mean an exposure of about 15 roentgens a year, or between 400 and 600 roentgens per working lifetime. The commission has agreed that exposure of a substantial fraction of the population to this much radiation is undesirable. Accordingly, while adhering to the permissible exposure of 0.3 roentgen per week, the latest recommendations of the ICRP state that it is inadvisable for an individual to receive more than 50 roentgens up to his age of 30, 100 roentgens up to age 40, and 200 roentgens up to age 60. This means that individuals who are exposed to radiation at the maximum level will be allowed to work only one-third of the time. In effect, the normal daily working level is reduced by a factor of about 3.

This will not be as difficult to carry out as might at first appear, since most of the large atomic energy and other radiation establishments in this country are already operating at exposure levels considerably below even the new reduced amount. It is rare for workers, even today, to be exposed to more than about one-fifth of the present permissible amount.

The new recommendations will, however, introduce a penalty on those installations that insist upon exposing their workers to the maximum permissible weekly amount. Under the new rules, such workers may be exposed to this level for only one-third of their working time, the penalty thus taking the form of intermittent and hence uneconomic use of personnel. The inducement will therefore, be strong for such installations to improve their protection facilities to the point where the maximum radiation exposure will not exceed the newly recommended average levels.

NBS PARTICIPATION IN THE MEETINGS

The participation of the National Bureau of Standards in the international protection program dates from 1928, the year in which the ICRP was formed. Since then, the Bureau's radiation research program has grown steadily in variety and scope. It now includes the gathering of basic radiation data with the 50-million-volt betatron and 180-million-volt synchrotron, theoretical studies on radiation, penetration, and diffusion, development of instruments, for detecting and measuring radiation, and publication of handbooks on methods of safe handling of X-rays and radioactive nuclides. An accelerated program also has been started on the study of protection against neutrons.

The Bureau's participation, together with other representatives from the United States in the work of the two international commissions was markedly increased as a result of the recent meetings. In the case of the Bureau, this appears not only in its preparation of a portable X-ray standard, but in the parts assigned to the following NBS staff members in the work of the commissions. L. S. Taylor, chief of the NBS division of atomic and radiation physics, was renominated for an additional 3-year term as chairman of the ICRU and as a member of the ICRP. H. O. Wykoff, chief of the radiation physics laboratory, continues as member of the ICRP committee on protection against X-rays generated by voltages up to 3 million volts. He has for several years been chairman of the corresponding subcommittee of the NCRP. Dr. Wykoff was also nominated as a member of the ICRU and chairman of its committee on standards and measurements of radiological exposure.

W. B. Mann, chief of the radioactivity laboratory, was nominated cochairman of the ICRU committee on standards and measurement of radioactivity. H. F. Attix, member of the X-ray laboratory staff, was named to the ICRU committee on standards and measurement of absorbed dose. Mrs. S. Raskin, staff

member of the radiation physics laboratory, attended the meetings as technical secretary to the chairman. H. W. Koch, chief of the betatron laboratory, continues on the ICRP committee on protection against X-rays above 3 million volts, beta rays, gamma rays, and heavy particles, including neutrons and protons. S. W. Smith, chief of the radiological equipment laboratory, was nominated as a new member of the ICRU committee on standards and methods of measurements of characteristic data of radiological equipment and materials used in diagnostic and therapeutic radiology.

EXHIBIT 5. COMPTES RENDUS, PAGES 3134–37, JUNE 1956

(Translation from French)

Radiobiology:[1] An indispensable reduction of the tolerated dosage recommended by the International Commission for Radiological Protection. Note by M. Pierre-Octave Robert, presented by M. Jacques Trefouël.

The recommended tolerance dosage; i. e., maximum permissible concentration (suggested) by the 1953 Congress amounts to a cumulative annual dosage of 15 roentgens and to a cumulative dosage of 450 roentgens.

The annual dosage is a dosage which would be genetically dangerous in 30 years; the 30-year dosage would be 50 percent fatal (if absorbed in 24 hours) and in 30 years would cause a shortening of life by 3 to 8 years.

At a time when France and the entire world will see a considerable increase in the number of nuclear centers, the personnel protection problem becomes one of the greatest importance.

A. Maximum permissible concentration:

(*a*) The maximum permissible concentration formerly allowed was 0.1 roentgen per working day.[2]

(*b*) At the London Congress of 1950 and the Copenhagen Congress of 1953 the International Commission for Radiological Protection reduced the maximum permissible tolerance to 0.3 roentgen per week in the open air, or to 0.06 roentgen per working day.

B. The cumulative annual dose and the cumulative annual dosage for a generation of 30 years.

We shall determine these dosages—assuming that the tolerated dosage is reached every day.

We recognize that in nuclear study centers, that this tolerated dosage is only rarely reached, although it may be accidentally exceeded.

On the other hand, however, in the neighborhood of atomic piles and experimental nuclear reactors, one must consider the personnel who control the operations; the chemists and physicians who do the work can be exposed daily to a dosage which they incorrectly believe to be a safe dosage.

This is why we have felt it ncessary to draw up the following table:

Cumulative dosage							
		per year of			for 30 years		
daily	weekly	50 weeks	48 weeks	40 weeks	50 weeks	48 weeks	40 weeks
0.06r	0.3r	15r	14.4r	12r	450r	432r	360r

C. What do these cumulative dosages represent?

1. The cumulative dosage in 30 years, on the order of 400 roentgens, represents a dosage which would be 50 percent fatal if it were absorbed in 24 hours in a spot contaminated by an atomic bomb. The same cumulative dosage over 40 years represents a 100 percent mortal dosage under the same conditions.

2. For comparative purposes, we may say that for a period of 30 years the natural sources—the soil and cosmic radiation—supply a cumulative dosage of 3 roentgens at sea level. By way of exception, the inhabitants of Tibet, where the cosmic radiation is more intense, absorb a cumulative dosage of 5 roentgens per 30-year generation.

---

[1] From Académie des Sciences, séance du 25 uin 1956, pp. 3134–3137.

[2] "r" concerns a quantity of X-rays or gamma rays; for general radiation (X, γ, α, β, neutrons) "rem" is used.

8. Comparison with experimental explosions of atomic bombs. The United States Atomic Energy Commission has established that the total quantity of radiation absorbed by Americans from all atomic explosions was—on February 15, 1955—0.1 roentgen, this for a total of 50 bombs exploded over a 4-year period. Finally, we may state that if atomic tests were to continue for another 30 years at the same rate, an average American would absorb approximately 0.75 roentgen in addition. What does this 0.75 roentgen represent in comparison with 400 roentgen of accumulated tolerance.

D. The genetic effects.

Several English and American documents give accounts of the work of Dr. H. J. Muller, a prominent geneticist, who believes that a doubling of the mutation rate of genes from generation to generation might bring about disastrous results. Dr. H. J. Muller believes that the received dosage must be limited to a quarter of the dosage which doubles the mutation rate. The AEC laboratory at Oak Ridge has determined the doubling dosage for mice. Experiments carried out lead to the conclusion that this dosage is 50 roentgens.

Extrapolating for human beings was believed possible, despite the uncertainties which this extrapolation causes by the fact of variations from one genus to another. Dr. H. J. Muller thus arrives at a maximum dosage per generation of 12.5 roentgens. This dosage is exactly the size of the dosage which would be absorbed in a year by a worker who absorbs the maximum permissible concentration daily. What would be the effects at the end of 30 years?

E. Effects on longevity.

It is certain that estimates of this sort can only be rather indefinite, as they are based on rather controversial statistical methods.

Statistical studies based on mortality estimates (due to all possible causes) have been carried out by Dr. Hardin Jones and Dr. K. Z. Morgan at Berkeley and Oak Ridge, respectively; in one case for an exposed population, and in the other for an unexposed population. They give results which agree very nearly on a factor of 2.

The result of this estimate is that if the dosage of radioactivity is given uniformly over a long period, that the expected length of life is shortened in the first case by 3 days per roentgen and in the other by 6 days per roentgen.

By elementary calculations, one can obtain—from a figure of 450 roentgens for the cumulative dosage for 30 years—a shortening from 1,350 to 2,700 days, and for the dosage of 360 roentgens a shortening of from 1,080 to 2,160 days, hence a definite shortening of life by 3 to 8 years from the dosages cited above (exactly 2.97 and 7.5 years—the uncertainty of the base figures has led us to round off to 3 years and 8 years).

We may note that these figures are relative to a very weak dosage of radiation such as those produced by experimental explosions.

The mortality percentage increases much faster than the dosage.

CONCLUSION

The maximum permissible concentration figuring in the recommendations of the International Commission for Radiological Protection is much too large, and it may represent, for personnel working permanently in nuclear centers and nuclear study centers, a serious danger.

It is certainly such possibilities as this which have caused the Harwell Study Center to take protective measures which limit the dosages received by workers at the center to 0.25 roentgens annually, a dosage which—as Sir John Cockroft states—is one-sixtieth of the internationally permitted concentration.

Our standpoint seems to be well justified, for at the last meeting of the International Commission for Radiological Protection at Geneva, the following suggestions were made:

A. For workers:

1. That the weekly dosage of 0.3 roentgen remain unchanged.
2. Protection services must see to it that the cumulative dosage does not exceed 5 roentgens annually.

B. For the population:

Here a more prudent position has been taken; the dosage has been reduced by one-tenth or 0.03 roentgen.

It is felt that this security factor is sufficient for sparse populations near (nuclear) centers.

For greater population densities, the dosage may be reduced to 0.2 or 0.3 roentgen annually.

Finally, the greatest preoccupation, of course, is for the consequences for the mass of the population.

Nevertheless, we believe that the dangers which threaten researchers cannot be neglected.

These projects cannot be discussed except at the forthcoming Mexican Congress, on July 25 next, and even this is not certain, considering the lively discussions which took place at Geneva.

A reduction of the annual maximum permissible tolerance appears indispensable and a decision in this sense must be energetically pursued.

EXHIBIT 6. REPORT OF MEETING OF ICRP, GENEVA 1956, STAFF TALK AT NBS, JUNE 1956

(Transcription of the tape recording of talk given to the Atomic and Radiation Physics Division staff by L. S. Taylor on June 1, 1956. This is an unedited discussion and is not for publication)

This is a brief review of some meetings which took place in Geneva last month and attended by a number of the members of our staff. These were the meetings of the International Commission on Radiological Protection, and the International Commission on Radiological Units and a meeting with a few members from each of the two Commissions with the World Health Organization.

The International Units Commission was established under the auspices of the First International Congress of Radiology, 1925. The Commission has been responsible for the development of the units used in radiation measurement. It also deals with problems of radiation measurement and standardization.

The Protection Commission was formed under the same auspices in 1928, and has been in continual operation ever since. I think it could be said quite properly that the Internatioanl Protection Commission has been responsible for the setting of the permissible exposure levels that have been used over the world, for some time now of the order of 25 or 30 years. The problem of protection, of course, is becoming more and more complicated as time goes on and I will review briefly a little of the background leading up to some changes that have been introduced by the International Commission meeting this past April.

The first specific permissible exposure levels were set by the ICRP in 1934, and at that time the level was given as two-tenths roentgen per day, whole body exposure. In the United States in about 1935 we lowered the level to one-tenth roentgen per day. Then in 1947 the National Committee on Radiation Protection which is the responsible body in this country for the establishment of safe working levels for radiation, reviewed a good deal of information that had become available during the Manhattan District days and again lowered the permissible exposure to three-tenths of a roentgen (or three-tenths of a rem) per week. In 1950, the general principles of this lowered permissible exposure were adopted by the International Commission and in 1953, recommendations similar to those of the United States national committee were reaffirmed and considerably extended.

The basic philosophy regarding radiation protection for individuals remains essentially the same with one important modification resulting from our 1953 meetings. This new modification has been discussed at some length for several years by the International Committee as well as the NCRP in this country, but was never put forward actively because here we have felt for some time that there has not been sufficiently definitive data leading to a quantitative lowering of the permissible exposure levels. Now, there are various factors that enter into the philosophy of permissible exposure or permissible dose. One is the question of detectable injury to the individual, and it has been this primary characteristic that has formed the basis for permissible exposure levels under occupational conditions. The present permissible occupational exposure of three-tenths rem per week is based primarily on consideration of a level which will not produce detectable injury to an individual during his lifetime.

Now, there has been nothing very much said in the setting of these levels about other problems such as genetic effects. They have, nevertheless, been considered—not simply passed by. Another problem that is basic to the question of permissible exposure is the short- or long-range genetic effects and I will return to these in a moment. There is also the question of the shortening of the life span. All of these questions have been considered at considerable length by the National Committee on Radiation Protection in this country as

well as by the International Commission. I will not go into any great detail on the genetic problem because I have a brief discussion on that at one of our staff meetings here just before we went to the Geneva meeting. I will, however, remind you that any radiation exposure of the genetic reproductive system will produce irreversible damage, and this can be passed on from one generation to another. Most of the experience in this field is based on animal experiments; there is very little information on man although some is gradually coming out of the Hiroshima-Nagasaki studies that are being made. There is very little doubt as to the basic fact that genetic damage is irreversible but I should like to emphasize that any quantitative information on man is extremely scant and nebulous. The really important factor in genetic damage is not so much the single individual as the whole population. The thing that really counts is the amount of radiation that is absorbed by the whole population or at least that part of the population which one expects normal crossbreeding.

Now, in 1952, the International Committee met in Stockholm for the primary purpose of discussing the genetic aspects of radiation exposure. There were several geneticists, among other people, there and at this time we considered the problem of exposure of whole population groups. At that time the estimates for exposures per individual, averaged over the whole population, ranged from 3 to 20 roentgens. There was one school of geneticists that set 3 and one that set 20 and there were some others in between. This appeared to represent to some extent the split of uncertainty among the geneticists themselves. In any case, suppose you were to take a value of 10 roentgens per person averaged over the whole population. This would mean you would sum up the total radiation exposure of the whole population, divide it by the number in the population; if this exceeded 10 roentgens, the geneticists believed we would have an unacceptable amount of genetic injury. At the Stockholm meeting in 1952, it was agreed that the present rates of exposure that we were working with were acceptable and the problem was not critical. This was reaffirmed with some minor reservations at our meetings last April. It was also recognized that with problems of fallout, widespread expansion of nuclear power, waste disposal, etc., time might begin to run out on us before too long. In spite of this, the International Commission felt that we would not be justified in setting a permissible average exposure level per person for the whole population.

In the last few years, there has been increasing evidence regarding the effect of radiation exposure on the expected life span of individuals. This was also considered in 1952 in Stockholm and again in 1956 in Geneva but again it was felt that the information for the most part was quite limited and did not provide grounds for a quantitative lowering or limitation of the permissible exposure levels. As a matter of fact, there is very little or maybe no serious effect of such radiation exposure with regard to life span insofar as small exposures to small areas of the body are concerned. For example, heavy overexposure of the hand is not going to have any serious effect on life span. On the other hand, where you expose the whole body to radiation some effect on the life span may be expected—a lowering of the life span. This type of effect is not very well understood, and it is not cumulative in the ordinary sense of genetic effects. I think the general belief is that radiation exposure somehow or other prematurely ages or makes one a little bit more susceptible to disease. These things of course, all contribute to an average shortening of life span.

It is rather interesting that there is actually some evidence that for very small dose rates to the whole body there might be some lengthening of the life span. This is, of course, based on animal experiments. However, I certainly would not recommend people living in a light atmosphere of radiation in the hope of living longer. Also, the effect of radiation with regard to life span is much greater for rather large, acute doses as compared with small chronic doses. Some of the best information on this question has been obtained from a study of leukemia among radiologists. It has been found that in comparing physicians who are radiologists and physicians who are carrying on normal medical practice, there is roughly a 10 percent shortening of the life span over the number of people who have been examined. This has to be treated very carefully, however, because the people who have been examined are the older radiologists; the younger ones are still living so you can't tell anything about their life span. The other radiologists have undoubtedly been exposed to many, many, many times the quantity of radiation that we feel is safe today and consequently this 10 percent figure as related to our present allowable exposures might have little significance. It has been agreed by the National Committee and by the Inter-

national Committee that the evidence is not sufficiently conclusive in this respect to warrant a quantitative lowering of the permissible exposure.

In spite of this lack of quantitative evidence, the problem was very seriously considered again with regard to making some lowering of the permissible exposure. I must say that I feel that the commission bowed a little bit to public clamor. There is an enormous amount of public pressure with regard to radiation exposure and I almost have the feeling that this limitation, which I will come to in a few minutes, may be regarded in some measure as slightly political. I don't mean political in the Government political sense, but political in the sense of being a good policy even though the foundation for it is moderately limited. Now in this whole problem of deciding upon a permissible radiation exposure level, we have to consider the sources of radiation. For example, at the present time, we have the fallout problem. This is one that is very much in people's minds. It was decided in a discussion of this that the increased radiation exposure to the population, as a whole, from fallout from tests made in this country and Russia is probably insignificant at the present time. This does not mean that it might not become significant later but certainly at the present time it is not to be seriously worried about in comparison with other exposures.

We then have occupational exposure in industry. By and large this is well-controlled exposure. The industries are very keen to insure that their working people are not overexposed and here we have a rather good radiation control program on the whole. Most of the large atomic energy plants, large industrial plants, and our own laboratory here already operate and have for many years operated at levels that are very much below the permissible level which we recommend as being safe. This problem may become more critical with the more widespread development of nuclear power.

A great deal depends on how we solve some of our waste problems and some of our normal exposure problems. As I mentioned a couple of months ago, I feel rather strongly that one of the serious limitations in the development of nuclear power will probably have to do with the efficiency with which we can control the radioactive waste disposal.

In the medical field we have another large source of radiation exposure. In some respects, this may be regarded as more critical than the others and in large areas much less well controlled, certainly, than in industry. This, however, varies. For example, in this country at the present time, we have about 3,000 radiologists using X-ray equipment and by and large these persons use X-rays with a reasonable degree of intelligence. They have some knowledge as to how much radiation they are using and they know something about protection so that we do not have to worry too much about the radiologists. On the other hand, we have another group including general practitioners, of which there about 15,000, using X-rays in this country. These people have very little knowledge about radiation protection and radiation dosage and in addition most of the working conditions that they have to live with are such as to militate against good protection practice. Even more serious than this is about an equal number totaling some 15,000, I believe, of osteopaths and chiropractors who are using radiation equipment. They very probably know substantially less about the problem than the general practitioner. Last but not least there are about 65,000 dentists who are using X-rays. It is possible for all of these people to provide adequate protection for themselves and for their patients just by applying principles that are already well known and adequately covered in recommendations in either the National Committee on Radiation Protection in this country or the International Commission over the world.

There has been a lot of difficulty in some local areas because people have learned about the effect of radiation exposure on life span. I have received several letters indicating that people are refusing to have dental examinations made because it exposes them sufficiently to shorten their life span by say 1 week. This is probably pretty silly but it does indicate something of what is happening in the public mind. In the first place, even an unreasonably large dental exposure is for the most part pretty well limited to the head. It is very different, as far as life span is concerned, from a whole body exposure. It is true the whole body gets some exposure but it is quite small. One would wonder as to whether we should be more concerned about a nebulous week's extension of one's life, on the one hand, or dying of some kind of an infection, on the other hand. In any case, there is a great deal to be done in the way of improving protection in these fields.

So much for the backbround and the need with regard to protection. I will come next to the primary change that was made in the protection recommendations in Geneva.

As I have mentioned, and I assume most of you know, the present basic level of exposure for the whole body is 3/10 rem per week for both internal and external exposure. This weekly limit has not been changed. As far as the individual is concerned, this is still regarded as a completely safe exposure. On the other hand, we have recognized to some degree these other effects, namely genetic effects and shortening of life span. As a result we have put a further limitation on this weekly exposure. Now if you allow the 3/10 rem per week, this would be equal to roughly 15 rems per year. If you consider that a person is going to work from age 20 to age 60, or 40 years, this would add up to something of the order of 600 rems for 40 years. If people actually worked to this level for a whole body exposure, there is no doubt, or very little doubt, that there might be some effect, however difficult to ascertain, on their life span. Certainly, if anything approaching this amount of radiation were received by the gonads during the reproductive period of a person's life, this would mean a very large exposure as far as genetics are concerned. To provide some further control on exposure we left the basic weekly figure the same but added a decade limitation such that up to age 30 we will allow a total exposure of 50 rems; up to age 40, 100 rems; and up to age 60, 200 rems.

The new figures of 200 rems compares with 600 rems at present so that insofar as continued exposure to radiation is concerned, we have in effect lowered the exposure limit by a factor of 3. Thus if someone wants to work at the full level of three-tenths rem per week, but not indefinitely, no harm is likely to result to him personally and not too much to his progeny. But he can only do this for a third of his working lifetime. If a person is employed continually in radiation work, this essentially means that the shielding has be so designed as to provide 3 times as much protection as we have been accustomed to using up to the present time. Thus while our basic level remains the same, in effect this amounts to a reducing of the working level by a factor of 3.

This is at best a lumping together of a lot of fairly uncertain factors and finally coming out with about as well-educated a guess as we know how to make. In some place or other, you certainly have to draw a line between no radiation exposure at all, which is what the geneticists would prefer, and what is reasonable and compatible with the advantages of radiation. These new limits will not, as far as we know, have any serious effect on our atomic energy industry. As far as we know, the atomic energy plants in this country are already operating at levels that are at least this low and in many cases lower. The principle bind may be in some of the industrial operations where management has, for the sake of economy, provided the minimum protection to stay within the law as it were. It will also probably crowd some of the medical setups.

Another problem that was discussed at some length by the National Committee and the International commission numerous times in the past, has to do with a setting up of a national or international registry of radiation exposure. In theory this looks like a nice idea. From the straight scientific point of view, a good registry of radiation exposure would have an enormous value in providing us later on with information on some of the long-range effects we are interested in. It was discussed again in great detail in Geneva and finally it was decided that for practical reasons it just could not be recommended. I might point out that in some countries like England, New Zealand, and Sweden, they have systems there which might make it possible to set up a registry of radiation exposure. Probably New Zealand and Sweden are the two closest to this because they already have some degree of governmental control over the use of all radiation equipment. However, in a country of this size, the task seems almost impossibly large.

Also, there is another difficulty certainly at the present time and probably until we have some strict control over radiation usage. One of the important sources of radiation exposure is that applied by general practitioners. Here we cannot expect for many, many years, at best, to have any really good idea of what exposures these people are using. They do not know themselves. They have no techniques by which you can really estimate the exposure given in a GI examination. The exposure might be 10r for a good operator; it might be 200r for a careless operator, and as long as you have information that is sloppy at source, there is no use in setting up a careful system for recording it.

In the matter of permissible concentrations of radioactice materials in air, the body, and water, the International Commission set up a substantial list of

about a hundred in 1953. To this there will be added about 70 more radio nuclides for which we now can give some reasonably good information on permissible concentrations. The new levels for the International Commission will be the same as those that have already been tentatively adopted by the National Committee in this country. For internal exposure, the base figure of three-tenths rem per week remains the same, for individual organs. There are, however, some special conditions for which lower exposure levels have been recommended. For example, where the genetic system constitutes the critical organ for a particular isotope or group of isotopes, the permissible exposure level will be one-tenth rem per week, or a third of the present value. If the whole body is the critical organ for internal emitters, it will also be one-tenth rem per week. The body burdens of radioactive materials are still based on the figure we have used for many years, namely, an accumulation of one microgram of radium in the body.

With regard to the International Commission, the membership has remained about the same; there were two new people added to the Main Commission. The subcommittees have remained about the same although there have been a few people added to those. Incidentally, a Russian was added to the membership of one of the committees operating under the Main International Commission. There has been a new committee set up to deal with problems of waste disposal. This is under the chairmanship of Dr. Straub, a member of the Public Health Service who until recently has been working at Oak Ridge.

With regard to our own relationships with the protection program, I have been continued as a member of the Main Commission. Wyckoff continues as a member of the X-Ray Protection Subcommittee, and Koch continues as a member of the High Energy Particles Subcommittee.

(Mr. Taylor's statement—continued.)

One of the recommendations made by the International Commission on Radiological Protection in 1956 was the dose limitation for occupational workers of 50 rems up to age 30, and 50 rems per decade thereafter. This averages to about 5 rems per year, but in plant operations and design, strict adherence to a 5-rems-per-year average is extremely difficult. In addition there was the fear that this yearly average figure might be enacted into law and for this reason the NCRP sought an interpretation that would allow more latitude in this use.

A suitable means for accomplishing this appeared to be the establishment of a permissible occupational exposure based on a total accumulated dose in relation to the age of an individual.

EXHIBIT 7. NATIONAL BUREAU OF STANDARDS TECHNICAL NEWS BULLETIN, MAXIMUM PERMISSIBLE EXPOSURES OF RADIATION TO MAN, VOLUME 41, PAGES 17–19, FEBRUARY 1957

MAXIMUM PERMISSIBLE RADIATION EXPOSURES TO MAN

A PRELIMINARY STATEMENT OF THE NATIONAL COMMITTEE ON RADIATION AND MEASUREMENT

The accompanying preliminary statement of the National Committee on Radiation Protection and Measurement (NCRP) presents in brief form the essential changes introduced by its new recommendations on the safe limits of radiation exposure. In making the new recommendations, the Committee reviewed its past recommendations in the light of increased knowledge about the long-range effects of radiation exposure on the genetic makeup and life expectancy of man.

The NCRP, an advisory group of experts in various phases of the radiation field, is sponsored by the National Bureau of Standards. The Committee is made up of representatives from the following organizations: American College of Radiology, American Dental Association, American Industrial Hygiene Association, American Medical Association, American Radium Society, American Roentgen Ray Society, International Association of Government Labor Officials, National Bureau of Standards, National Electrical Manufacturers Association, Radiological Society of North America, United States Air Force, United States

Army, United States Atomic Energy Commission, United States Navy, and United States Public Health Service. The reports of the Committee are published in the NBS Handbook series.

Because the new recommendations of the NCRP will affect material contained in many of its handbooks, revisions of the latter will be undertaken at an early date. Until these revisions are completed and ready for publication, an effort will be made to prepare for each handbook a simplified statement of the changes needed to comply with the new recommendations. These summary statements will be released to the technical journals for publication as they are completed, and will be used with the handbooks now in stock. The full and detailed changes will be incorporated in the revised editions of the handbooks.

Since the publication of NBS Handbook 59 on Permissible Dose From External Sources of Ionizing Radiation, the National Committee on Radiation Protection and Measurement (NCRP) has continued the study and review of its recommendations,[1] particularly with respect to genetic effects and the possible shortening of average life expectancy due to radiation exposure of a larger fraction of the population. The NCRP proposals resulting from these studies had an important influence on the decisions reached by the International Commission on Radiological Protection (ICRP) in Geneva in April 1956,[2] which resulted in a general lowering of the maximum permissible accumulated dose (MPD for occupational radiation exposures, as well as for exposures of the population as a whole. These changes are in accord with the informal agreements reached by the ICRP in Stockholm in 1952.

The NCRP has now agreed upon the formulation of revised recommendations on maximum permissible doses which integrate the national and international views for practical application. The Committee is pleased to note that the findings of the ICRP are reinforced by the important information and data provided in the subsequent reports of the National Academy of Sciences and the British Medical Research Council.

The changes in the accumulated MPD are not the results of positive evidence of damage due to use of the earlier permissible dose levels, but rather are based on the desire to bring the MPD into accord with the trends of scientific opinions; it is recognized that there are still many uncertainties in the available data and information. Consideration has also been given to the probability of a large future increase in radiation uses. In spite of the trends, it is believed that the risk involved in delaying the activation of these recommendations is very small, if not negligible. Conditions in existing installations should be modified to meet the new recommendations as soon as practicable, and the new MPD limits should be used in the design and planning of future apparatus and installations. Because of the impact of these changes and the time required to modify existing equipment and installations, it is recommended on the basis of present knowledge that a conversion period of not more than 5 years be adopted, within which time all necessary modifications should be completed.

DEFINITIONS

For the purposes of this preliminary statement, the following tentative definitions are given:

Controlled area.—A defined area in which the occupational exposure of personnel to radiation or to radioactive material is under the supervision of a radia-

---

[1] The recommendations of the NCRP are regularly published in the NBS Handbook series, copies of which may be purchased from the Superintendent of Documents, Government Printing Office, Washington 25, D. C. The following handbooks containing NCRP recommendations are currently available at the indicated prices per copy: H42, Safe Handling of Radioactive Isotopes, 20 cents; H48, Control and Removal of Radioactive Contamination in Laboratories, 15 cents; H49, Recomemndations for Waste Disposal of Phosphorus 32 and Iodine 131 for Medical Users, 15 Cents; H51, Radiological Monitoring Methods and Instruments, 20 cents; H52, Maximum Permissible Amounts of Radioisotopes in the Human Body and Maximum Permissible Concentrations in Air and Water, 25 cents; H53, Recommendations for the Disposal of Carbon 14 Wastes, 15 cents; H54, Protection Against Radiations From Radium, Cobalt 60, and Cesium 137 (revision of H23), 25 cents; H55, Protection Against Betatron-Synchrotron Radiations up to 100 Million Electron Volts, 25 cents; H56, Safe Handling of Cadavers Containing Radioactive Isotopes, 15 cents; H58, Radioactive-Waste Disposal in the Ocean, 20 cents; H59, Permissible Dose From External Sources of Ionizing Radiation, 30 cents; H60, X-ray Protection (revision of H41), 20 cents; H61, Regulation of Radiation Exposure by Legislative Means, 25 cents.

[2] See Meetings on radiation units and protection, NBS Tech. News Bul. 40, 102 (July 1956).

tion safety officer. (This implies that a controlled area is one that requires control of access, occupancy, and working conditions for radiation protection purposes.

Workload.—The output of a radiation machine or a radioactive source integrated over a suitable time and expressed in appropriate units.

Occupancy factor.—The factor by which the workload should be multiplied to correct for the degree or type of occupancy of the area in question.

RBE dose.—RBE stands for relative biological effectiveness. An RBE dose is the dose measured in rems. (This is discussed in the forthcoming report of the International Commission on Radiological Units and Protection.)

MPD RECOMMENDATIONS FOR OCCUPATIONAL CONDITIONS (CONTROLLED AREAS)

1. *Accumulated dose.*—The maximum permissible accumulated dose, in rems, at any age, is equal to 5 times the number of years beyond age 18, provided no annual increment exceeds 15 rems. Thus the accumulated MPD=5 (N−18) rems where N is the age and greater than 18. This applies to all critical organs except the skin, for which the value is double.

2. *Weekly dose.*—The previous permissible weekly whole-body dose of 0.3 rem, and the 13-week dose of 3 rems when the weekly limit is exceeded, are still considered to be the weekly MPD, with the above restriction for accumulated dose.

3. *Emergency dose.*—An accidental or emergency dose of 25 rems to the whole body, occurring only once in the lifetime of the person, shall be assumed to have no effect on the radiation tolerance status of that person. (See National Bureau of Standards Handbook 59.)

4. *Medical dose.*—Radiation exposures resulting from necessary medical and dental procedures shall be assumed to have no effect on the radiation tolerance status of the person concerned.

MPD RECOMMENDATIONS FOR THE WHOLE POPULATION

5. The maximum permissible dose to the gonads for the population of the United States as a whole from all sources of radiation, including medical and other man-made sources, and background, shall not exceed 14 million rems per million of population over the period from conception up to age 30, and one-third that amount in each decade thereafter. Averaging should be done for the population group in which crossbreeding may be expected.

RECOMMENDATIONS FOR INTERNAL EMITTERS

6. In controlled areas, the permissible radiation levels for internal emitters will conform to the general principles outlined above. Where the critical organ is the gonad or the whole body, the maximum permissible concentrations of radionuclides in air and water will be one-third the values heretofore specified for radiation workers. Where single organs other than the gonads are regarded as the critical organ, the present maximum permissible concentrations will continue. For individuals outside of controlled areas, the maximum permissible concentrations should be one-tenth of those for occupational exposures. (Other changes in the maximum permissible concentrations for radionuclides may be introduced because of additional information developed since the publication of National Bureau of Standards Handbook 52.)

DISCUSSION OF REVISED RECOMMENDATIONS

7. The MPD for occupational exposure is based on the absence of detectable injury to the individual. It remains at its present level of 0.3 rem per week for the whole body. Where the dose in any week exceeds this value, a dose of 3 rems in 13 weeks may be accepted. The 13-week period may start at the beginning of the calendar quarter or the beginning of the week during which the permissible weekly dose was exceeded.

8. The rules given in Handbook 59 will be continued for operational and administrative purposes, but some of the rules will be modified by provisions related to an average yearly limitation of occupational exposure to external sources of ionizing radiation of 5 rems to the blood-forming organs, gonads, and lenses of the eyes, and of 10 rems to the skin. The use of "5 rems" in the statement of the revised rules is for the purpose of design and administration.

The critical limitation will be that defined for the total accumulated dose in paragraph 1 above.

9. If a person's occupational exposure is documented or otherwise known with reasonable certainty, he may be permitted to use his reserve exposure in accordance with paragraphs 1 and 2 above. In all other cases, he shall be assumed to have received his maximum accumulated dose as indicated in paragraph 1 above.

10. It is considered that with the current and proposed low levels of occupational exposure, it is presently not necessary to make special allowance for medical exposure in conjunction with occupational exposure. This consideration may later become important. The effects of medical exposures have long been considered by this committee to be the responsibility of the attending physician; it is his responsibility to evaluate medical radiation exposure in relation to the health of the individual. (See National Bureau of Standards Handbook 59.)

11. In the determination of the population dose in the vicinity of radiation sources, proper consideration should be given to occupancy factor and to workload. The exposure of individuals outside of controlled areas may be integrated over periods up to 1 year.

12. While at the moment it is not feasible to determine the average exposure for the population with any reasonable accuracy, the adoption of some figure is necessary for planning purposes. For the immediate future, it may be assumed that the total integrated RBE dose received by all radiation workers will be small in comparison with the integrated RBE dose of the whole population. Furthermore, persons outside of controlled areas, but exposed to radiation from a controlled area, constitute only a small portion of the whole population. Therefore, if this small portion is assumed to receive yearly an average per capita dose of 0.5 rem, the total dose to the whole population from man-made radiations is not likely to exceed 10 million rems per million of population up to age 30. (This assumes a dose of 4 million rems per million of population over this age period from background radiation.)

Dated: January 8, 1957.

(Mr. Taylor's statement continued.)

In accordance with this idea, the NCRP now recommends that the maximum permissible accumulated dose in rems for occupational exposure be 5 times the number of years of age of an individual over 18 (age 18 being the time when an individual is allowed to be engaged in radiation work). This can be expressed by the relationship MPD = 5 (N–18) rems. The old permissible value of 0.3 rem per week or 15 rems per year will be continued, provided the accumulated dose as expressed by the formula above is not exceeded. Also the 25-rem emergency dose will be continued.

The relationship of the new permissible dose levels to the older levels is illustrated in the accompanying figure. (See p. 784.) The upper shaded area is bounded by the permissible dose relationship that existed from 1935 to 1947. according to this, a person would be allowed 0.1 rem per day, and accordingly could accumulate a dose of 600 rems by an age of approximately 38 years.

The center shaded area indicates the accumulated dose that would have been received according to the standards used during the years 1947 to 1957, when the allowance was 0.3 rem per week. On this basis, a person could have received slightly over 600 rems by age 60.

The lower region indicates the limits in accordance with the 1957 recommendations on the basis of which a person would be allowed to receive a maximum of only 210 rems by age 60.

The way in which a person may receive his occupational dose under the new recommendations is quite flexible. So long as his accumulation at a given age remains within the lower white area, he will be complying with the new recommendations. If he works well below these limits for a given period, he may essentially build up a reserve, and then if circumstances demand, he can accept an occupational exposure at the rate up to 15 rems per year so long as he stays under the age-prorated limitation. Furthermore, if an individual having had no previous radiation experience were to start work at, say, age 35, he can be exposed at the level of 15 rems per year for a number of years until he begins to approach his age-prorated limitation. By following this exposure plan, an individual is prevented from receiving his accumulated dose too rapidly, particularly at the younger ages where, for genetic reasons, his dose reception has greater significance. Typical ways of distributing this dose are indicated by the plots

shown in the white area. (It should be pointed out that while this white area is labeled "same exposure region", we do not mean to imply that any radiation exposure is safe, but rather that it complies with the standards.)

For persons receiving nonoccupational exposure in the environs of radiation sources the permissible levels have been set at 0.1 of the values for occupational exposure. Strictly speaking, this should be an average exposure over a large number of individuals, because here again it does not make any difference if a few people receive more than the average, provided that others receive correspondingly less. This is a higher allowable figure than for the population as a whole, but according to present estimates it is not expected in the foreseeable future that more than 1 percent of the population is likely to be exposed to radiation at these levels. In computing the average exposures, adequate allowance should be made for occupancy factors, and factors which take into consideration the fraction of the time that the plant is emitting radiation. Making this type of allowance is difficult legally, as evidenced by the current AEC regulations. On the other hand, too strict a legal interpretation of this philosophy will cause undue hardship on the radiation industry.

For the population as a whole, the NCRP has recommended an average exposure of 14×10^6 rems per million of population up to age 30, and one-third of that amount per decade thereafter. Here again it should be noted that this is an average figure taking into consideration a large population group, and it is not correct to reduce this number to an exposure for a single individual. It might be pointed out that the number 14 may be raised to 15. This is mainly for making the arithmetic easy. There is no significant difference between 14 and 15 as far as our present knowledge is concerned.

It may be instructive to have a rough picture of how the dose to our population will be distributed according to present knowledge. The following table shows this.

Percent of population	Radiation source	Man-rem per million population
100	Background	4,000,000
100	Medical	1–5,000,000
1/8	Occupational	150,000
1	Installation environs	150,000
100	Fallout	200,000
Total		5–9,500,000
Balance		8–4,500,000
Total		14,000,000

Exhibit 8. Current Situation With Regard to Permissible Radiation Exposure Levels, American Nuclear Society, December 1956

ADDRESS GIVEN BEFORE AMERICAN NUCLEAR SOCIETY, DECEMBER 17, 1956

Lauriston S. Taylor, Atomic and Radiation Physics Division, National Bureau of Standards, Washington, D. C.

This discussion will deal primarily with permissible radiation exposure levels in relation to occupational exposure in industry. While these levels are intimately related to general population exposure levels, this phase of the problem will not be discussed in detail.

For the past 25 years this country has based its permissible occupational exposure levels on the recommendations of the National Committee on Radiation Protection and the International Commission on Radiological Protection. In both cases the exposure levels have been based primarily on the effect of radiation exposure upon the individual. Reduced to the simplest terms, this has amounted to a figure of 0.3 rem per week over the period of employment. The current permissible weekly level is based on the premise that a whole body exposure of 0.3 rem per week for an indefinite period of time would not produce any detectable harmful effect on the individual.

It should be pointed out that at the time these levels were set, extensive consideration was given to the effect of this degree of radiation exposure on our genetic system and upon the average expected life span of the occupational ir-

radiated population. Handbook 59, which set forth the proposals of permissible exposure from external radiation, made numerous references to the fact that this basic requirement for permissible exposure might have to be changed in the future. This is typified by the following statement, "As the applications of atomic energy expand and the number of exposed individuals increases, genetic effects will become more important. Accordingly, it may be expected that at some time in the not too distant future a reappraisal of the situation will become necessary. On the basis of present knowledge of the genetic effects of radiation, it may be predicted that any future revision of permissible doses to the gonads of young persons will be downward. This should be borne in mind, and unnecessary exposure to radiation should be avoided at all times." Similarly, the effect of radiation on the average life expectancy was considered. The knowledge of a few years ago was vastly less than today, and even today the question is one in which there is considerable quantitative doubt.

The present permissible exposure levels took into consideration the fact that only a small fraction of the population would be subjected to radiation exposures approaching the maximum permissible levels. No allowance was made for the fact that the great majority of radiation exposures would be considerably below the permissible levels. By neglecting this fact an additional safety factor was automatically introduced. It is undoubtedly estimating on the high side if one ventures to suggest that there may be as many as 500,000 occupational workers in this country. This would be about one-third of 1 percent of our population. Considering occupational exposure alone, in comparison with medical and other sources of exposure, the total exposure to this group of people would be regarded as genetically relatively unimportant.

The report of the National Academy of Sciences on the genetic effects of radiation indicated that an exposure of 1,000 roentgens has produced in the radiological profession a shortening of about 5 years in the average life expectancy. This figure is probably as good as any that can be attained, yet it must be borne in mind that it is based on statistics including most of the early radiologists, who worked under conditions of almost zero protection. Many people believe that the estimated figure of 1,000 r average exposure for these persons is in all probability low and that a more realistic figure may be of the order of 3,000 or 4,000 r. It will be impossible to ever determine what this exposure was.

According to the present levels of 0.3 r per week or 15 r per year, a radiation worker could receive as much as 600 r in 40 years of working lifetime or about 300 r up to the end of his genetically important period. There can be little argument that in the light of present knowledge this amount of exposure may be unreasonably high, yet as far as the individual is concerned, there is no evidence at present that exposures at these rates have caused individual detectable injury. In fact there is no evidence that the higher levels of 100 r per year from 1928 to 1936, or 36 r per year from 1936 to 1947, have resulted in detectable injuries either. Of course one must point out that average shortening of life expectancy might be essentially regarded as an undetermined injury.

Even with the low levels of 0.3 rem per week in us since 1947, most atomic energy plants found that they could operate satisfactorily at levels ranging from one-third to one-tenth of this value without seriously interfering with their operations. It is erring on the safe side, to say that in no large atomic energy plants, in this country, has the average exposure per individual exceeded, or in even most cases approached, 0.1 r per week.

It should also be pointed out that when one considers the problem of radiation effect on life span, one thinks of whole-body exposure. In fact a substantial fraction of the persons receiving occupational exposures in the atomic energy, medical and industrial field have only small portions of their body exposed. Under such circumstances the effect on life expectancy is very much less.

The National Committee on Radiation Protection in 1946, and the International Commission on Radiation Protection in 1950, undertook extensive studies of the whole question of permissible exposure and it was during this period that the present levels were set. In 1952 there was a special meeting of the ICRP, in conjunction with the Joint Committee on Radiobiology of the International Union of Pure and Applied Physics, for the specific purposes of studying the genetic effects of radiation exposure. Participating in this were a number of geneticists from several countries, and the basic problem before the Commission at that time was consideration of an average population dose to the gonads, during the reproductive period. The acceptable values at the time ranged from 3 to 20 rems over and above that due to natural and background radiation.

(These bracket the figure suggested by the National Academy of Sciences report in 1956.) At the time it was considered by the ICRP that the fraction of the population receiving radiation exposure was so small that immediate concern over the total population dose was not necessary. It is believed that many of the members still feel much the same way, but on the other hand there has been and still is clear recognition of the fact that this situation will almost certainly change as our radiation uses throughout the world increases.

At meetings of the ICRP in Geneva in April of this year the genetic problem were again considered and a figure of amount 10 rems of manmade radiation was recommended as a reasonable average per capita dose for the future. It should be emphasized that within our present practices it is not likely that the increase of occupational exposure would contribute very importantly to this total exposure level.

It has been decided by the NCRP on the basis of present evidence that the most important new limitation should be one relative to gonadal exposure to individuals during their reproductive lifetime. For this it was considered that the occupational exposure a dose of about 100 rems up to age 40 would not involve an unacceptable risk. Similarly an exposure of up to 250 rems by age 70 would not be regarded as unacceptable. In the case of exposure received beyond the reproductive age, the further influence of such exposure would in the main be through its effect on expected life span. Operationally, it would seem to be just about as easy to continue beyond age 40, the same permissible levels allowed below age 40.

In these considerations it is clear that the emphasis has shifted from the exposure of the individual to exposure of the population. At the same time it has to some extent shifted from a weekly or monthly exposure level to the exposure accumulated over the individual's lifetime.

TABLE I (DISTRIBUTION OF POPULATION DOSE) (P. 818)

In principle, permissible exposures such as I have just mentioned may be considered as adequate for all occupational and regulatory purposes. Unfortunately in practice this is not possible and as a result it has been necessary to develop a series of derived permissible exposure levels over varying periods of time, and in relation to the age of the individual.

The difficulty up to now in dealing with a single number giving the individuals total permissible lifetime exposure, is introduced because of the fact that the safety *recommendations* of a few years ago have now entered our legal machinery and are now *legal requirements* backed up by varying degrees of enforcement. For the 25 years beginning with the appearance of the first NCRP Handbook in 1931, radiation safety control in this country was on the basis of recommendations backed up by voluntary compliance and good sense. It must be admitted that there were times when neither compliance nor good sense prevailed, but in the great majority of situations it did. A substantial number of legal cases involving overexposure to radiation, were settled one way or the other on the basis of NCRP handbooks without any of these handbooks ever being legally adopted in the form of codes or laws.

The basic scientific aims and information regarding permissibe radiation exposures have been well understood for a number of years. On the other hand, there have been situations where the information was capable of misinterpretation by people who were inexperienced in the field. Partly as a result of this there has been increased tendency on the part of industry and by State and Federal Government to call for strict codification and the development of radiation protection rules wherein a situation is either black or white. Here begins our trouble.

Let us consider as acceptable a total accumulated exposure of 250 rems over a period of 50 years, up to age 70. Now it is obviously impossible, with any means that we now know of, to measure and record this exposure for each individual. Therefore, the wise operator might decide to make his measurements over a period of 10 years, assuring that no employee would receive over 50 rems over a period of 10 years. This is still impractical because we have no instruments that an individual can wear for 10 years to record his dose. Furthermore, there may be occasional unscrupulous employers who may allow an individual to receive his 10-year dose of 50 rems in 3 years and having done this simply fire the man because he is no longer useful in the radiation plant.

For the purposes of design and operation, one might want to integrate the exposure over a shorter period of time, say 1 year, in which case the average

allowable amount would be 5 rems. This is also difficult to control but it is suspected that before too long adequate instrumentation will be obtainable such that this can be done within adequate accuracy limits. At least as far as plant operations are concerned the level of 5 rems per year is a much better figure to work with.

The importance of limiting the exposure to individuals during their child-bearing age has been mentioned. For this purpose the NCRP is recommending a permissible exposure of approximately 60 rems up to age 30, and an additional 50 rems up to age 40.

Now here again it is important to assure adequate distribution of this dose over time. If one considers that 50 percent of the children are born to parents by the time they reach age 30, and 90 percent by the time they reach age 40, it is clearly more important to curtail exposure at the lower end of this age range than at the upper age range. There would be a large difference in the total genetic damage due to an exposure of 50 rems at age 20, as compared to the same exposure at age 30. At the age of 40 this exposure would only affect 10 percent of the genes that might be expected to be transmitted. Consequently there is some wisdom in stating that for operational purposes the average occupational exposure of individuals should not exceed 5 rems per year.

But even here there are difficulties. Suppose that the NCRP were to recommend 5 rems per year for the basic permissible level as compared with the present level of 0.3 rem per week. As soon as this figure is even mentioned it will find its way into various laws and regulations. Everything automatically becomes black or white and any individual who may be so unfortunate as to receive 5,001 rems in any 1 year might think he had legal grounds for seeking redress from his employer. This is, of course, sheer nonsense and yet it is difficult to develop a law in this field in which there is adequate latitude for such reasonableness. The NCRP has worried a great deal about this problem and various suggestions have been put forward.

Consider the cost to a plant operation if a legal limitation of 5 rems per year to the individual worker. Plant management would be foolish to plan their operations in such a way that part or all of its workers would be allowed to take a dose closely approaching 5 rems per year. Experience has demonstrated that surely 1 or 2 people are going to accidentally exceed this and even though we know that a slightly higher exposure is without harm the employee might seek redress. Because of this fear, the plant must plan its operation such that in general they will not exceed, say, 40 or 50 percent of the permissible exposure. This can be very costly and time consuming and could seriously retard the atomic-energy industry.

It has also been suggested that the yearly limit be specified as 5 rems plus or minus 20 percent. This would certainly simplify plant planning and operations, but I am very doubtful as to how and whether this could be dealt with to the satisfaction of our legal authorities. Another suggestion has been to specify a total exposure not exceeding 50 rems in 10 years delivered at an average rate not exceeding 5 rems per year. Here, again, this situation is wide open to abuse or difficulty in legal interpretation. For example, an employer could allow an individual to receive 25 r in each of 2 years and then lay him off under circumstance which would make him unemployable in the radiation industry. Also this would be unacceptable because one should not allow an individual at the beginning of his reproductive age to receive this large dose. If he is to have a large dose, it is much better that he receive this after the conception of his last child and this, of course, changes with age.

Another alternative is to specify the 5 rems per year average but with the further stipulation that no one be allowed to receive in excess of 10 rems in any consecutive 2 years. Even this would allow some abuse, but such a provision would vastly simplify plant operations. For example, if an occupational individual received, say, 6 rems in 1 year, it would be up to the plant to insure that he could receive no more than 4 rems in the following year. If one decides on an average figure of 5 rems per year, the plant will design accordingly. The plant will possibly go further than this, since control over a year is not always easy. It may well, for purposes of simplicity, make its designs so as not to allow the exposures to exceed 0.1 rem per week, which is one-third of the present maximum permissible exposure.

All of the discussion so far has led us to one almost inescapable conclusion—namely, that the maximum permissible exposure levels are going to be reduced to one-third of what they are at the present time. One could then ask why all the fuss about the various exposure levels that have been discussed above?

Except for the exposure limitation for genetic reasons in the 20- to 40-age bracket, all of the levels are so low as to make it virtually impossible to make any distinction between dose delivered over a few months or even a few years.

One could well ask, Why not take the basic figure of 250 rems up to age 70, and leave the rest of it up to the plants—or even do the same for 50 rems per 10 years? The difficulty, however, is that various individuals will interpret the limits in various ways and, unless the permissible dose is integrated over a relatively short period, a given employer might use up all of the employee's permissible exposure, making it impossible for the employee to shift positions or to continue work in his chosen field. The various numbers mentioned above may be included in the new recommendations of the National Committee on Radiation Protection. It must be borne in mind, however, that the permissible levels that are expressed in terms of 1 week, 13 weeks, a year, or even 10 years, are regarded as numbers to be used for design and operational purposes. There is nothing sacred about any of them, and yet failure to introduce such time-dose limitations will encourage the introduction of such a high degree of nonuniformity of permissible exposure in the radiation field as to make employment in radiation work unattractive.

Where a plant or individual can provide adequate assurance that his monitoring and recording methods are adequate, he should be allowed the widest latitude in the use of permissible-exposure levels with his employees. I do not know how this can be worked out legally, but I feel fairly certain that in operations of any substantial size, it would pay the employer to have adequate measuring and recording systems and then be allowed wide latitude in his use of any of the various permissible levels that I have mentioned above.

The main difficulty may occur with the small users of radiation sources where there is transient employment and where the cost of monitoring equipment may be incommensurate with the cost of his operation. For such individuals permissible-exposure levels integrated over 1 week, or, at the most, 3 months, would in all probability be the most feasible.

In conclusion, let us look briefly at the pattern of exposure levels that were agreed upon by the executive committee of the National Committee on Radiation Protection at its meetings in September and December of this year.

The basic figure of 0.3 rem per week, together with the penalty allowance of 3 rems per 13 weeks, presently in use will be continued. So also will be the allowance of 15 rems per year (allowing for 2 weeks' vacation).

These basic figures will, however, be subject to a further limitation to insure that the dose is not accumulated too rapidly, or reaches totals per individual that are not considered acceptable. If we allow an accumulated dose, over 50 years, of about 250 rems up to age 70, this would amount to an average of about 5 rems per year.

Most of the operational problems can be solved by means of a simple formulation that implies the building up of a bank of reserve exposure that may be called upon as needed. The new requirement will be that at any given age of 18 or over, an individual may be allowed to accept a dose such that his total accumulation will not be in excess of five times the number of years over 18.

TABLE II (STATEMENT OF NEW RECOMMENDATIONS) (P. 818)

Thus, at any time, a person's exposure must equal or be less than 5 (N–18) where N is the person's age. This automatically holds down the exposure at the younger ages where it is most critical. It gives leeway at the older ages where it is less critical. Thus, if a person starting work at age 18 receives only 1 rem per year for 5 years, his total will be 5 rems, as compared with 25 rems permitted. He has thus banked a reserve of 20 rems. Should occasion then demand a larger dose, he can take up to 15 rems in the next year and still have a reserve of 5 rems in the bank.

If a person starts radiation work at an older age, he will have automatically built up a reserve and can take larger annual doses—so long as the accumulation remains less than the age prorated maximum. This procedure eliminates the need for the present rule allowing larger exposures for persons over 45.

CURVE ILLUSTRATING USE OF RESERVE EXPOSURE (SEE P. 784)

For design or planning or operational purposes, plants may wish to use average weekly, monthly, or quarterly levels and do their monitoring accordingly. Under the new rule this will be permitted. Where it is desired to keep monitoring and recording procedures to a minimum, it would probably be wise, in many

cases, to operate on a weekly or monthly basis anyway. The choice of procedure will depend largely upon the economics of any particular situation.

Where a person's exposure in prior employment may be unknown or undocumented, it will be presumed to have been the maximum permitted up to his particular age.

It might be pointed out that the levels above need not be modified by the acceptance of one emergency exposure of 25 rems during that person's lifetime.

Also it might be noted that these exposure levels are not modified by any radiation exposure received for medical reasons. On the other hand, it would be prudent for the employer to take any especially large medical exposures into consideration in the assignment of an individual to radiation work.

The rules given in Handbook 59 will be continued but some of them will be modified by provisos related to a yearly limitation of 5 rems to the blood-forming organs, gonads and lenses of the eyes, and to a limitation of 10 rems to the skin.

Permissible radiation levels for internal emitters will conform to the general principles already outlined. Where the critical organ is the gonads or the whole body, the maximum permissible concentrations for air and water will be one-third the present values specified for radiation workers. For persons living in the neighborhood of controlled areas, the maximum permissible concentrations should be further reduced by a factor of 10. Where single organs are regarded as the critical organ, the present concentrations may be continued.

TABLE I.—*Maximum permissible accumulated dose up to age 30=14,000,000 rems per million persons*

Source:	*Rems per million persons*
Natural	4,300,000
Medical	5,000,000
Occupational	150,000
Plant environs	150,000
Fallout	200,000
Total	9,800,000
Balance	4,200,000

TABLE II.—*Basic whole-body maximum permissible dose (occupational)*

1. Three-tenths rems per week or 15 rems per year.
2. Not to exceed at age N an accumulate dose of 5 (N–18) rems.
3. One emergency exposure of 25 rems in a lifetime.
4. MPD not modified by medical exposure.

(Mr. Taylor's statement—continued.)

The standards described above apply to conditions where the whole body, the lens of the eye and the gonads are exposed. Where the blood-forming organs may be the critical organs, these may in some circumstances provide the basic limitation.

The above standards apply to all kinds of radiation but here again we are handicapped in practical applications by lack of adequate knowledge of the RBE.

When dealing with various sources or kinds of radiation incident upon a particular organ, each is treated separately and the dose from each is added.

The rate of delivery of the dose is relatively unimportant so long as we stay within the basic age-prorated limitation described above.

Partial body exposures may be larger depending upon circumstances. For example, where only the hands and feet are exposed, the permissible dose to the skin may be 15 times larger than indicated by the formula above. Similarly, where the skin of the entire body is irradiated by low penetration radiation the permissible levels may be twice those given in the formula. There may be other such variations and other specific organs under certain conditions.

A detailed discussion of this question is given in Handbook 59. Although this handbook was published several years ago most of the arguments contained in it still apply. A revision of the handbook is now in preparation and while this will contain most of the old material, it will also include revisions to take into consideration the new accumulated dose concept.

STANDARDS OF PERMISSIBLE DOSE FROM INTERNAL SOURCES OF RADIATION

The previous discussion has indicated some of the more essential points relative to the maximum permissible dose for external sources of radiation. For sources of radiation inside the body, the protection standards are related to and are consistent with those for external sources. Unfortunately there is relatively little quantitative knowledge of the exact effects of internal radiation on man although a great deal of information has been obtained from animal experiments.

Much of our basis for the standards for internal dose is related to information obtained from the deaths several decades ago of the radium dial painters in New Jersey. This question will undoubtedly be discussed in greater detail by one of the subsequent witnesses. In the case of the radium dial painters there was substantial uncertainty about the kinds and quantities of material that contributed to the dose and the results might be seriously influenced by the presence of large fractions of mesothorium in the dial paint. Even today there is some uncertainty in the proper RBE to use for radium under these circumstances. In using this information as a basis for permissible dose the most conservative extremes have been used, and there is not unreasonable likelihood that our present permissible body burden for radium may, in fact, be unnecessarily low.

Many isotopes tend to go to and localize in certain body organs or tissues. The permissible dose therefore is based on the dose to those organs (see Handbook 52). Where more than one organ may be affected the most critical one is usually chosen. For many isotopes a different base is employed. For pure gamma emitters and some beta emitters the base level is chosen as an amount which would give the organ a dose not in excess of 0.3 rem per week. The results of using this base are not completely consistent with those using the radium base but the difference is not critical. For Sr–90 the radium base is used even though strontium is a beta emitter and radium primarily an alpha emitter. Allowing for this difference in base and the uncertainty in RBE, it is possible that the maximum permissible body burden for Sr–90 may be conservative by a factor as large as 15. It is almost certainly conservative by a factor of 5.

Body burdens are based on the concentration in certain areas where localized damage may originate. In some circumstances you may have maximum body burdens of different isotopes in different organs where there is no interplay between the organ functions. At present there is relatively little knowledge on this. It is an area where much research and statistical study is needed.

EXHIBIT 9. NATIONAL BUREAU OF STANDARDS HANDBOOK 52, MAXIMUM PERMISSIBLE AMOUNTS OF RADIOISOTOPES IN THE HUMAN BODY AND MAXIMUM PERMISSIBLE CONCENTRATIONS IN AIR AND WATER, MARCH 1953

D. FACTORS THAT DETERMINE THE HAZARDS OF RADIOISOTOPES

The factors that determine the hazards of the various radioisotopes are as follows:

1. Quantities available

None of the radioisotopes except those occurring naturally presented problems until the age of high-voltage accelerators, nuclear reactors, and atomic bombs. From the standpoint of common use and quantity available, I–131, P–32, Co–60, Si–90, C–14, S–35, Ca–45, Au–198, Ra–226, Pu–239, and uranium present the major problems of irradiation inside the body.

2. Initial body retention

Large fractions of some elements such as iodine, strontium, and sodium are absorbed when they are taken into the body by any of the several routes and when available in their common chemical forms. In the case of elements like plutonium and uranium, only a small fraction is absorbed in the gastrointestinal tract. Therefore, the greater retention would increase the hazards from the first group as against those of the second. In dealing with the inhalation of radioisotopes, unless information specific to the radioisotope is available, it is assumed in the case of soluble compounds that 25 percent is retained in the lower respiratory tract. From this tract it goes to the blood stream, and a part of this goes to the critical organ within a few days. Fifty percent is held up in the upper respiratory tract and swallowed, so a fraction of that swallowed also reaches the critical organ. In the case of insoluble compounds, it is assumed that 12 percent is retained in the lower respiratory tract, which is usually taken as the critical organ

when considering the inhalation of insoluble compounds. The rest is eliminated by exhalation and swallowing.

3. Fraction going from blood to critical body tissue

Some elements in the blood stream are eliminated rapidly from the body, whereas large fractions of others are deposited in certain body organs.

4. Radiosensitivity of tissue

Some body tissues are more radiosensitive than others. For example, the lymphatic tissue and bone marrow are much more radiosensitive than muscle or nerve tissue. Therefore, in equal concentrations an element like plutonium is more hazardous than uranium because the plutonium concentrates in the most sensitive part of the bone, whereas the uranium goes to other portions of the bone, the kidney, and various other relatively insensitive organs.

5. Size of critical organ

For a given number of microcuries of a radioisotope in a critical organ, it follows that the smaller the organ the greater the concentration and the greater the dose delivered to the critical tissue. Iodine presents a much greater problem than sodium, since iodine is very selectively absorbed in a small body organ, the thyroid gland, whereas sodium is rather uniformly distributed throughout the body. In many cases the radioisotope is deposited in a large organ but localized in a small portion of that organ, so that, in effect, the mass of critical tissue may become very small.

6. Essentiality of the critical organ to the proper function of the body

Some body organs are either not essential to the body function, or, when they are damaged or removed, special steps can be taken to supplement or compensate for their reduced function. It is for this reason that damage to the bone marrow, kidneys, eyes, etc., would represent perhaps a greater hazard than equal tissue damage to the thyroid gland.

7. Biological half-life

Some elements like radium, plutonium, and strontium are deposited in critical body tissue where the rate of turnover is very slow or the biological half-life is many years. These radioisotopes are much more hazardous than the radioisotopes like carbon, sodium, and sulfur (C–14, Na–24, and S–35), which have biological half-lives of a few days or weeks. The principal methods of elimination of radioisotopes from the body are by way of the urine, feces, exhalation, and perspiration. Usually elimination is much more rapid before the radioisotope is translocated from the blood to a more permanent area, such as the bone, than afterward. This time is usually of the order of a few days to a few weeks. After this initial period the elimination rate becomes more nearly exponential, and the application of the term "biological half-life" has real meaning.

8. Radioactive half-lives of intermediate length

The mixture of U–238+U–234+U–235 that occurs in nature does not present much of a radiation hazard (if the radioactive daughter elements are removed); because with the very long, controlling half-life of U–238 of 4.5×10^{9} years, it requires 1.5×10^{6} g. of this uranium isotopic mixture to make up a curie of alpha activity. The maximum permissible amount of this mixture in the body (given in table 3, A) is 0.02 μc. This corresponds to about 0.03 g., and it is unlikely that a person would get this much uranium in his body. If he did, it probably would result in a chemical hazard before the detrimental effects of radiation would show up. The U–233, with a half-life of 1.62×10^{5} years (100 g./curie [1]), and Sr–90, with a half-life of 25 years (6.3×10^{-3} g./curie), are much greater hazards. In the case of Sr–90 in equilibrium with Y–90 the maximum permissible amount of Sr–90 in the body is 1μc., or only 6.3×10^{-9} g., which is about 10^{-13} of the mass of the human body. This concentration is so small and the rate of elimination so low once a maximum permissible amount of S–90 in equilibrium with Y–90 becomes fixed in the bone, that it is then very difficult if not impossible, to make accurate estimates of the amount present. Therefore, if there is exposure to such radioisotopes, every precaution should be taken to minimize the body uptake, and urinalyses should be made frequently so that the amount going into the bone can be estimated from concentrations in the urine

[1] g/curie$=7.66\times10^{-9}At_r$, in which A=atomic weight, and T_r=radioactive half-life of the radioisotope in days.

during the early portion of the period of exposure, when the elimination rate is much higher.

At the other extreme of specific activity, radioisotopes with very short half-lives do not present much of a hazard unless the exposure is maintained by continuous uptake, since the activity of such radioisotopes when deposited in the body soon decays to an insignificant level. As a rule-of-thumb one can remember that the activity is reduced to less than 1 percent after 7 half-lives (2^{-7}= 0.008=0.8 percent). Examples of these short-lived radioisotopes are P-32, with a half-life of 14.3 days (3.5×10^{-6} g./curie), and N-16, with a half-life of 7.35 sec. (10^{-11} g./curie). In general, radioisotopes with intermediate radioactive half-lives of about 5 to 50 years present the greatest hazards, other factors being equal and the danger diminishes for radioisotopes with greater or smaller radioactive half-lives. The most important period of exposure to laboratory personnel is from the age of 20 to 45, because very few younger persons are employed by laboratories that handle radioisotopes, as they are not frequently subject to large internal doses of radioisotopes; and many of the chronic effects of radiation do not manifest themselves until 15 to 25 years after the radiation insult (and 45+25=70 years, which is the average life span). The younger the person who accumulates the radioisotopes in his body the greater the hazard and the more serious the accumulation of intermediate-lived radioisotopes like Pu-239, Ra-226, Sr-90, and Po-210 in the body. It is for this reason that added precautions should be observed not to take into the body radioisotopes like Sr-90 that might be translocated to the fetus; contaminated clothing should not be worn home, where it may present a radiation hazard to young members of the family; and dangerous quantities of radioisotopes should not be discharged into the air or into the public water supplies, where the population as a whole may be exposed. It is generally true also that fast-growing cells of the body are more subject to radiation damage than fully developed cells, and this is a good reason to be more cautious in permitting the accumulation of radioisotopes in young people or in women in the child-bearing age.

9. Energy of the radiation produced by the radioisotope

The radiation hazard associated with a radioisotope deposited in the body is proportional to the average energy of disintegration weighted for the biological effectiveness of the radiation. The total effective energy per disintegration of the Ra-226 plus half[2] the energy of Rn-222 and its alpha-emitting daughter products is 14.5 Mev. The energy per disintegration of Pu-239 is 5.16 Mev, and so (on an energy basis alone) when equal curie amounts of Ra-226 and Pu-239 are deposited in the body, one would expect Ra-226 to be about three times as hazardous as Pu-239. (Actually, it is thought that the fact that Pu-239 is more densely concentrated in the radiosensitive portion of the bone than Ra-226 more than compensates for this energy difference, so that the reverse may very well be true. The maximum permissible amount of Ra-226 (in microcuries) in the body is taken to be about 2.5 times that of Pu-239.) Another interesting comparison is obtained by examining some of the beta- and gamma-emitting radioisotopes. In a comparison of H-3 with Na-24 it is noted in table 4 that the effective energy per disintegration of H-3 is 0.006 Mev, and the effective energy per disintegration of Na-24 is 2.7 Mev. On an energy basis alone the maximum permissible amount of H-3 in the body would be 450 times that of Na-24. In this case both Na-24 and H-3 are assumed to be rather uniformly distributed in a similar matter throughout the body, so that the effective energy per disintegration is the principal factor determining the relative biological damage from these two radioisotopes when deposited in the body. The ratio of the maximum permissible amounts of the two radioisotopes in the body (using values from table 3, B) is approximately inversely proportional to the ratio of the effective energies.

10. Specific ionization and attenuation of energy in tissue

As indicated in table 1 alpha particles are considered to be 20 times as damaging on an energy-absorption basis as beta or gamma radiation because of their high specific ionization. The specific ionization in air of a 1 Mev alpha is about 6×10^4 ion pairs per centimeter path, whereas that of a 1 Mev beta is only 45 ion pairs per centimeter path. It is considered that for most of the gross damaging effects of radiation the concentrated energy loss in tissue produced by

[2] Experiments of R. D. Evans have indicated that about half of the radon escapes from the body.

an alpha particle represents a greater hazard by a factor of 20 than the less dense energy loss in tissue represented by the greater penetration of beta and gamma radiation.

Beta radiation is absorbed mostly in the immediate vicinity of the atoms from which it is emitted, while the attenuation of gamma radiation of the same energy is much slower (e. g., if a beta emitter has a maximum energy of 2 Mev, a negligible fraction of the beta rays has the maximum range in tissue of about 1 cm. In the case of a 2 Mev gamma emitter, only about 3 percent of the gamma-ray energy is absorbed in the 1 cm. of tissue). Hence in a small organ most of the beta radiation emitted in the organ will be absorbed in the organ, whereas gamma energy emitted in the same organ will be absorbed in a much larger volume of tissue or escape from the body altogether. Alpha radiation is even more localized than beta. For example, almost all the energy of the 5.9 Mev alpha from At–211 is absorbed in the thyroid gland, where it localizes. An alpha ray must have an energy of about 7.5 Mev to penetrate the epidermal protective layer of skin about the body, which has a minimum thickness of about 0.07 mm. The range of a 70–key beta ray is about 0.07 mm. of tissue, so only a small fraction of 70 Kev beta rays will penetrate this protective layer. Therefore, hazards from alpha and low-energy beta radiation can be controlled by keeping alpha and low-energy beta sources outside the body.

To give some idea of the complexity of the problem the following factors enter into a determination of the isotope hazard.

1. Quantity available.
2. Initial body retention.
3. Fraction going from blood to critical body tissue.
4. Radiation sensitivity of the tissue.
5. Size of the critical organ.
6. Essentiality of the critical organ to proper function of the body.

Essentiality is difficult to define. The production of carcinogenisis in any organ would, in a sense, define essentiality since this would most likely result in death. On the other hand, irradiation of such organs as the eyes, gonads, or thyroid can produce damage to each without necessarily impairing other body functions at least to the point of causing death.

7. Biological half life.

This includes the physical half life of the radioactive material and the half life of the material itself within the body; in other words the time which it takes for the body to eliminate, by normal processes, 50 percent of the radioactive material that entered it.

8. Radioactive half lives of intermediate length.
9. Energy of radiation produced by the radioisotopes.
10. Ionization density and attenuation of energy and tissue.

Control of the radioactivity in the body is brought about through control of what is allowed to enter the body. Having determined the allowable amount in the whole body or in an organ, the procedure is to work backward to arrive at the concentrations in air, drinking water or food that if taken into the body continuously or intermittently would eventually build up to the allowable amounts. It should be pointed out that the maximum permissible concentrations and body burdens for occupational workers assume continuous intake for the working lifetime of the individual. Where the intake is not continuous larger concentrations may be tolerated.

In arriving at the maximum permissible exposures for man there are no safety factors included as such. Calculations are based on the best biological and clinical information available and are made as rigorous as possible. However, at each stage where any uncertainty exists the most conservative choice of values are chosen. In most cases this introduces a sort of safety factor. One of the largest uncertainties takes into account the individual variations between persons.

In getting the total effect of internal and external radiation on the body, each source is treated separately, and the summation from all sources is made with proper weighting. The organ dose for each source is summed up for the most critical organ. This addition is not entirely clean if more than one organ is involved, which is generally the case for external irradiation. As noted before, these additive effects need much more study but it is believed that present practices for the designation of maximum permissible dose are in the conservative direction.

RECOMMENDATIONS OF THE NATIONAL COMMITTEE ON RADIATION PROTECTION AND MEASUREMENTS

At the present time the National Committee on Radiation Protection and Measurements has prepared a list of maximum permissible concentrations for air, water, and the body for 100 radioisotopes. These are included in table III of Handbook 52. At the present time the committee is working actively on an extension of this list and it is expected that within a few months a new edition of the handbood will list over 300 isotopes. This same information will be used by the International Commission on Radiological Protection.

The maximum permissible concentrations in the revised handbook are, for the most part, not materially different from the old values, even though we have reduced the maximum permissible accumulated dose by a factor of 3. This reduction by a factor of 3 applies only when the whole body or the gonads is the critical organ. This will be important mainly for such radioisotopes as Na-22, Na-24, H-3, C-36, C-37, Br-82, A-37, and some of the noble gases.

The NCRP has recently reaffirmed its previous position that the dose to persons in the environs of radiation sources and outside of controlled areas should be 0.1 of the levels for occupational exposure. On a yearly basis that would amount to 0.5 rem per year. Even though there is some evidence that very young and very old persons may be somewhat more susceptible to radiation effects, no distinction is made between them and persons of intermediate age. This is possible because an average dose of 0.5 rem per year is so low (only a few times background) that many age differentials would average out. Also in this connection the dose in these uncontrolled areas should be averaged over the recipients and should not apply to the single individual. This admittedly has practical legal difficulties but the fact still stands that on the average it will do no harm for some people to exceed this while others have less. Partial body exposures are generally less important than are whole-body exposures, but there may be some important exceptions to this. Again this is an area about which relatively little is known at the present time. If we always consider that we are dealing with whole-body exposures we will continue to err in the safe direction.

EXHIBIT 10. ACUTE LETHALITY OF PARTIAL BODY IN RELATION TO WHOLE-BODY IRRADIATION, H. A. BLAIR, UR-462

THE UNIVERSITY OF ROCHESTER ATOMIC ENERGY PROJECT

By H. A. Blair

ABSTRACT

If to cause acute death from radiation the same amount of lethal substance or injury must be produced, whether the whole body or segments thereof are irradiated, it is shown that the reciprocal of LD_{50} for the whole body, will be equal to the sum of the reciprocals of LD_{50} for the separate segments, all doses being measured in roentgens. Existing data are compatible with this view but they involve irradiation of large segments of the body. For small segments undoubtedly the rule will fail. Some general aspects of partial body irradiation are discussed.

Partial body irradiation is of interest because it is common in occupational and accidental exposures, because it results from the ingestion of most radioactive materials owing to their inhomogeneous distribution and because of its possible use as a technique in studies of the nature of the injurious action of radiation.

One type of experiment which has been performed is determination of LD_{50}—30 days for a given strain of animals for whole body irradiation, for irradiation of a segment of the body and for irradiation of the remainder of the body excluding this segment.

If the segments of the body are A and B, respectively, the whole body is A+B. If the lethal action of the radiation is proportional to the dose and if the same level of lethal effect, Q, is required whether whole body or individual segments are irradiated then

$$Q=AR_A=BR_B=(A+B)R \tag{1}$$

R_A, and R_B and R being the lethal doses in roentgens and A, B, and A+B are now the products of the weights of the segments and the constants of proportionality converting roentgens to lethal effect.

On dividing the two right hand terms of equation 1 by BR_BR

$$1/R = (A/B+1)/R_T$$

but from (1) $$A/BR_B = 1/R_A$$

therefore $$1/R = 1/R_A + 1/R_B \qquad (2)$$

According to this equation and the hypotheses used, the reciprocal of whole body LD_{50} is equal to the sum of the reciprocals of the LD_{50} for irradiations of two segments which together include all of the body.

TABLE 1

Strain	Whole body		Head alone R	Body alone R	Head and body 1/R+1/R
	R	1/R			
Dba	500	0.0020	500	1,265	0.00280
Marsh	570	.00175	1,185	1,018	.00183
C57	550	.00181	1,300	858	.00194
C_3H	492	.00203	1,443	735	.00198

NOTE.—Data by Reinhard et al. (see footnote 1) on determinations of LD_{50}, R, for partial and whole body irradiation in 4 strains of mice. According to the hypotheses used here the reciprocals of cols. 2 and 5 should be equal.

Data by Reinhard et al.[1] giving LD_{50} in four strains of mice for head alone, body alone, and whole body are shown in table 1. It will be seen that agreement with equation 2 is fairly good except for the one instance in which LD_{50} for head and whole body are the same. One of these values is most probably in error on general grounds.

These results are compatible with the view that a given amount of a lethal effect or lethal substance is required to kill and that it is equally effective whether it is produced uniformly in the body or only in a segment thereof.

Equation 1 is compatible with the view, but does not require, that the total number of gram roentgens required to kill are the same whether delivered to the whole body or to a segment only; this because the constants of proportionality in A, B, etc., may, or may not be, proportional to the weights of their respective segments.

Information of this point is supplied by Kereiakes et al.[2] [3] who demonstrated by irradiating rats and mice through a protective grid with equal diameter apertures that the lethal dose in gram roentgens was nearly the same for irradiation of the whole body as for distributed fractions down to about 15 percent of the body. However, when the apertures were reduced in diameter while keeping constant the area exposed, the gram roentgen lethal dose increased. This latter effect was attributed to reduction of effectiveness of the injury by reparative actions occurring across the increasingly larger surface of normal tissue surrounding the irradiated as the apertures become small.

While the experiments just cited show that within fairly wide limits the gram roentgen lethal dose may be the same for whole body and segmental irradiation, when the segments represent all types of tissue, this is not true, according to Swift et al.[4] when the abdomen alone or the remainder of the body alone are irradiated. Their data are shown in table 2.

TABLE 2

	Whole body	Abdomen exposed	Abdomen shielded
R	650–750	1,025	1,950
kg. R	175	134	275
1/R	0.00143	0.00097	0.00051

NOTE.—Data of Swift et al. (See footnote 4.) LD_{50} in roentgens, R, and in kilogram roentgens, kg. R, for whole and partial body irradiation of rats of the Sprague-Dawley strain. Whole body LD_{50} is taken as 700 r in calculating 1/R. Acutally the reciprocal of 676 r is equal to the sum of the reciprocals for the segmental irradiations.

It will be seen that the sum of the reciprocals for partial body irradiations, 0.00148, is essentially equal to, 0.00143, the reciprocal of 700 r the average of the range of values 650 to 750 r given for whole body LD_{50}. Consequently these data conform to equation 2. However, the lethal doses in kilogram roentgens are quite different for the three modes of irradiation. Consequently agreement with equation 2 may be attributed, not to the necessity of equal gram roentgens, for lethality, but rather to the necessity for equal lethal effect or substance. These matters can be discussed most easily by generalizing equations 1 and 2.

Let Q=amount of lethal effect required. Let there be n segments of weight w_1, w_2, etc., requiring, respectively, for lethality the doses r_1, r_2, etc. Then if a_1, a_2, etc., are the constants of proportionality giving the effectiveness of the radiation in producing lethal effect per gram per roentgen in each segment

$$Q=a_1w_1r_1=a_2w_2r_2= \dots a_nw_nr_n=(a_1w_1+a_2w_2+ \dots a_nw_n)r \qquad (3)$$

the last term representing irradiation of all the segments together with lethal dose, r. The sum of the segments may or may not include the whole body.

On dividing the second and last terms by r and $a_1w_1r_1$

$$\frac{1}{r}=\left(\frac{1}{r_1}+\frac{a_2w_2}{a_1w_1r_1}+\dots\frac{a_nw_n}{a_1w_1r_1}\right)$$

But

$$\frac{a_2w_2}{a_1w_1r_1}=\frac{1}{r_2} \text{ etc.} \dots \frac{a_nw_n}{a_1w_1r_1}=\frac{1}{r_n}$$

Therefore

$$\frac{1}{r}=\frac{1}{r_1}+\frac{1}{r_2}+\dots\frac{1}{r_n} \qquad (4)$$

It will be observed that agreement of data with equation 4 imposes no requirement for equality of the products wr, or gram roentgen doses in equation 3, because the a's may be different. In the experiments of Swift et al.,[3] a, for the abdomen is twice as great as that for the remainder of the body. In other words twice as much lethal effect occurs in the abdomen per gram roentgen as in the remainder of the body.

The reason that the data of Kereiakes et al, show a wide range of equality of gram roentgens for lethality is, presumably, that similarly representative samples of all the tissues were usually exposed. When this condition is not fulfilled gram roentgens will vary.

A feature of equation 4 of some interest is its prediction with respect to the lethal dose for any segment in relation to that for the whole body. Let this be the *n*th segment. Then

$$\frac{1}{r_n}=\frac{1}{r}-\left(\frac{1}{r_1}+\frac{1}{r_2}+\frac{1}{r_{n-1}}\right)$$

or

$$\frac{1}{r_n}<\frac{1}{r} \text{ or } r_n>r \qquad (5)$$

That is, the lethal dose in roentgens for irradiation of any segment of the body, no matter how sensitive it may be, is always greater than the lethal dose in roentgens for the whole body.

As a corollary to this the lethal dose will always be increased by shielding part of the body and the increase will be greater the greater the sensitivity of the shielded part.

93299°—57—pt. 1——53

It has been implied thus far that the irradiated segments are mutually exclusive and this is necessary if the relations derived are to be obeyed. Furthermore, this condition can be met, by appropriate shielding, in fairly close approximation using external sources. With injected radioactive materials, however, if two varieties are administered alone and then in combination, the regions in which they accumulate may overlap. This is immaterial, however, providing each substance produces its effect independently of the other. It is of interest to consider two such materials.

Using the same notation as before

$$Q = a_1 w_1 r_1 = a_2 w_2 r_2 = \alpha a_1 w_1 r_1 + \beta a_2 w_2 r_2$$

the first terms representing LD_{50} for the two substances separately and the last term representing LD_{50} for the case in which the two materials are given togther in fractions α and β respectively, of the LD_{50} when given alone. Owing to the prolongation of dosage and simultaneous recovery r_1 and r_2 will be effective rather than real doses.

It will be seen that the above relation requires $\alpha + \beta = 1$. It is not to be expected, however, that this relation will be obeyed except for two materials of the same effective half-lives; otherwise their maximal effects will not occur at the same time and consequently will not be wholly additive. On this ground, therefore, it would be expected that $\alpha + \beta$ would usually be greater than 1. It is shown by recent work of Carsten and Noonan [5] however, that recovery from a primary radiation injury as measured by a second dose is faster in the rat when the abdomen and hind limbs alone, rather than the whole body, is irradiated. This suggests the possibility that recovery rate decreases as the irradiated volume increases. If this is true for radioactive materials it permits the possibility that the maximal acute injury from two materials of different tissue distributions acting together and affecting a larger volume of tissue would each be greater than when the materials acted alone. If so $\alpha + \beta$ might be less than 1. This case has been observed by Friedell et al.[6] who found that half LD_{50} of radioactive gold and of phosphorus administered together constituted almost LD_{100}.

It will be seen from these considerations that no simple additive relations are necessary to be expected for the acute lethality of mixed radioactive materials except when they have the same organ distribution and biological half-lives.

COMMENTS

The present analysis is compatible with either hypothesis that radiation produces a toxin which spreads to the whole body or, an injurious effect, confined for the most part, to the volume exposed.

If there is a toxin produced there is no evidence that it is combatted more effectively by nonirradiated than by irradiated tissue. An exception to this may be the spleen. However, its action may be wholly restorative of hemopoiesis rather than detoxifying. In any case spleen shielding is protective much out of proportion to the predictions of the hypotheses used here.

In this regard it is significant that shielding extensive areas of bone marrow does not alter the lethal level of injury in the unshielded segment of the body.

This analysis is compatible with the usual hypothesis that the lethal effects of radiation are in direct proportion to the dose but the proportionality constants are not the same for all tissues.

In the field of partial body irradiation more information is required especially with respect to long term effects. It is known that non-homogeneously deposited internal radioactive emitters cause shortening of life-span but the dose-effect relationships are not obtainable from existing data.

It is indicated by these results that the gram roentgen dose for lethality will tend to be the same for the whole body inhomogenously exposed, homogeneously exposed, and partially exposed. This rule will fail, however, in either direction when the average sensitivity of the exposed tissues is not the same as for the whole body. It will also fail, presumably, for irradiation of segments of the body, not essential to life, such as limb, which, with proper treatment, could be exposed to the extent of necrosis without leading to death of the whole organism.

(Mr. Taylor's statement—continued.)

A subcommittee of the NCRP is presently working on the gonadal dose from all internal emitters, including those which move relatively quickly through the body. This work is under the direction of Dr. K. Z. Morgan at Oak Ridge, and is an extremely complicated problem, the solution of which will require the most modern machine computation techniques. If this program is successful, it is hoped that the method will be extended to the determination of the skeletal dose which, according to the most recent information, is beginning to look more important, particularly in relation to fallout problems.

PHILOSOPHY AND BACKGROUND OF RADIATION PROTECTION

This part of the discussion will be covered only in outline since much of the supporting information is covered in the accompanying documents.

EXHIBIT 11. PHILOSOPHY UNDERLYING RADIATION PROTECTION, AMERICAN JOURNAL ROENTGENOLOGY, VOLUME 77, PAGE 914, MAY 1957 (MIMEOGRAPH COPY)

ADDRESS BEFORE THE NINTH ANNUAL CONFERENCE ON ELECTRICAL TECHNIQUES IN MEDICINE AND BIOLOGY, NOVEMBER 7, 1956

Lauriston S. Taylor, Atomic and Radiation Physics Division, National Bureau of Standards

In the broad sense, radiation protection is a problem that will touch the lives of most of us and more as time goes on, whether it be in connection with nondestrictive testing, with radiology, or with the production of nuclear power. The uses of radiation-producing machines and the use of radioactive materials will undoubtedly increase as time goes on, and radiation, as such, will become an increasingly important part of our national economy.

The general substance of the discussion [this evening] will have to do with the development of our philosophy of radiation protection. To do this in proper perspective, it will be desirable to review in some detail the early history of radiation protection, and the development of radiation-protection standards.

The term "radiation-protection standards" is used somewhat loosely and yet at the same time there is probably very little real uncertainty as to the broad meaning of the term. One normally thinks of a standard as being something rather firm, rather well understood, inflexible, accurately known, and reproducible. When a standard is mentioned, one immediately thinks of something like the standard meter-bar, carefully locked away in a vault and resistant to the changes of time; or of some accurately measurable quantity, such as the ohm or volt.

However, in the field of radiation protection standards, there are many unknowns and many uncertainties. They involve a great many assumptions that may have to be changed from time to time. In fact it would not be oversimplifying the case to state that our protection standards are essentially protection goals or objectives. Where it is possible to develop numbers to assign to some of the standards, these numbers are really more in the nature of a means to achieve some goal than the goal itself. Even the goal itself is difficult of

definition. It is primarily to determine the limits of radiation exposure to which the individual, or whole population, can be exposed without encountering risks incommensurate with the benefits to be expected from its use. Standards of safety go back directly to the individual who will be exposed to radiation. For this it is necessary to determine how much radiation he can absorb without injury to himself or to his progeny.

Knowing the complication of the human being as an organic structure, and the great difference in sensitivity between individuals, it is very easy to see why such a determination becomes an extremely difficult problem. To point up the difficulties, it may be helpful to review rather briefly some of the early background and philosophy leading to the development of standards of radiation protection. Much has been written on this subject and therefore only the high spots will be touched upon.

Radiation was recognized as a potential hazard to health soon after its discovery. Efforts to understand and curtail radiation exposure to individuals, were not begun seriously until the 1920's. One should bear in mind that it was not until 1928 that the world had a uniform and acceptable unit of radiation dose, namely the roentgen. Consequently, radiation-protection efforts and protection standards were, of necessity, on a purely qualitative basis. Until 1928, most radiation treatments were expressed in terms of fractions of an erythema dose—the amount of radiation that would cause a defined reddening of the skin. This in itself was a very uncertain factor, since it depended upon the energy of the radiation, the time over which it was delivered, the size of the irradiated field, and the amount of backscattering, not to mention the individual's idiosyncrasy with regard to radiation sensitivity. It was not until the midthirties that stray radiation exposure was measured quantitatively, thus making it possible to put radiation-protection standards on a reasonably firm quantitative basis. Interestingly enough, later efforts proved that these early standards were not grossly wrong.

One could venture the suggestion that if there is any basic standard of radiation protection it would be what is now referred to as the maximum permissible dose, or maximum permissible exposure of an individual. By maximum permissible exposure is meant the amount of radiation to which the whole body of an individual can be subjected over the period of his adult lifetime without producing in that individual any detectable harmful effects. For the occupational exposure of an individual to radiation, such a standard might be adequate, but as I will explain in more detail, another basic standard is needed for the exposure of the entire population—one that takes the genetic effects into consideration.

Parenthetically, it should be remarked that the old term "tolerance dose" that prevailed for many years is a complete misnomer. There is no such thing as a "tolerable dose of radiation." No radiation, other than for the treatment of disease, is known to be beneficial to man. Any radiation exposure received by man must be accepted as harmful. Therefore, the *objective should be to keep man's exposure as low as possible and yet, at the same time, not discontinue the use of radiation altogether.*

The big problem is to obtain some quantitative idea, as to the degree of harm that will result from exposure to various amounts of radiation.

As already mentioned, early permissible exposures were expressed in terms of the erythema. This followed as a result of a very few observations made on a very few people who had been overexposed to radiation, under conditions where there was some crude idea as to the amount of radiation involved. As a result of this, numerous proposals were made, and for a time served a useful purpose. For example, Mutscheller proposed as a "tolerable dose," one-hundredths of an erythema dose in 30 days. Others reduced this to one-thousandths of an erythema dose in 3 days. Sievert independently proposed one-tenth of an erythema dose per year, which was not appreciably different from Mutscheller's value.

Various attempts were made to place the tolerance dose on a sound physical basis. Glocker and Kaupp described a tolerance dose as that radiation level which would give just barely visible fluorescence observable in a completely darkened room by dark-adapted eyes. They also described it, as barely visible blackening of a "duplitized" X-ray film after an exposure to radiation of one hour. Mutscheller developed a simple but very inaccurate formula for computing erythema doses, for a given distance from the X-ray tube, for the useful beam. The number of erythema doses was given by the number of milliampere minutes, divided by 25 times the square of the distance.

Knowing as much as we do now about radiation, these standards look pathetic indeed, and yet they marked important milestones leading to our more accurate understanding of the problem. When one realizes that, on the basis of today's knowledge, an erythema dose under given conditions may vary from 270 to 1,000 roentgens over a range of 100 to 1,000 kilovolts, some visualization of the vast uncertainties in the early work might be had.

By the early thirty's such works as just mentioned were correlated and reconciled by the free use of safety factors—or just factors. Germany proposed the first quantitative expression of a permissible dose measured in roentgens, arriving at a figure of 10^{-5} roentgen per second as their so-called tolerance level of radiation. In 1934 it was possible, for the first time, for the International Commission on Radiological Protection to express permissible exposure in terms of roentgens. The value then chosen was two-tenth roentgen per day. In the United States in 1936 a somewhat lower level, namely one-tenth roentgen per day was adopted. This lower value was in part a result of the belief that there was not an adequate safety factor in the international recommendations.

It will be noted that the permissible exposures mentioned above were integrated over varying lengths of time, ranging over a period of 1 second to 1 year. Although precise information on radiation recovery is lacking, it is undoubtedly true that a given dose of some roentgens received in a period of a few minutes is probably more harmful to the individual than the same dose distributed evenly over a year's period of time. Therefore, while the various proposals for permissible exposure appear to reduce numerically to the same quantity, they were not, in fact, biologically equivalent.

Additionally, there is a serious administrative problem involved, when one compares the integration of a dose given over a few seconds or over a year. For example, according to the early German proposals, if at any time an individual is exposed to more than 10^{-5} roentgens in any one second, he would have exceeded his permissible dose rate even though this might only occur once in a year. This, of course, is nonsense. On the other hand, the problem of integrating a dose over a year's time could also present serious difficulties, depending upon the particular technique used. A person might be heavily overexposed during an early period in a year, yet this might not be detected until it was too late. It was through consideration of such reasons as these, that integration over a period of one day was adopted in the mid thirties.

In 1946, the National Committee on Radiation Protection undertook an intensive review of the whole problem of permissible dose. This review was instigated by the fact that, during the Manhattan District days, a tremendous amount of experimental and biological research had been carried out for the purpose of assuring safety to radiation workers; new biological data had become available. It was quickly realized that the value one-tenth roentgen per day, as used in this country, provided only marginal protection. There was increasing evidence, leading the committee to believe that the value should be lowered. At the same time, it was decided to review the question of the period over which the dose would be integrated. For technical, as well as administrative reasons, it appeared that integration over one day was unnecessarily restrictive. Integration over about 1 month appeared to be more reasonable and a compromise was finally reached at one week. The committee arrived at the recommendation of three-tenths roentgen per week as the permissible whole-body exposure to gamma rays and to moderate and medium energy X-rays. This value has since been adopted internationally.

There is one very important fact that I would like to emphasize at this point. From 1928 to 1936, the permissible exposure was one-tenth of an erythema dose or 50 to 100 r per year; from 1936 to 1948 it was 36 r per year; since 1948 it has been 15 r per year. Now, as far as I know, there is not a single case on record where an individual who has maintained his exposure within any of these limits, has developed any detectable injury that can be reasonably ascribed to that radiation exposure. One may ask with some reason, why, if this is such an imposing negative record, has there been a steady lowering of the permissible exposures, and why still further reductions are being considered. The reason for the 1948 change has been well documented in the NCRP report on the permissible dose from external sources of ionizing radiation. This was published as NBS Handbook No. 59.

One point not mentioned there is the fact that through the availability of better technical data required for shielding design, it has now become possible to provide this better shielding at costs that are not unreasonable. In other words, better protection was readily obtainable—why not use it? It might be

remarked that most of the large atomic energy installations have applied further factors of safety of 5–10 to the lower levels introduced in 1948.

Thus far in my discussion, the problem of radiation exposure to the individual has been considered only under essentially occupational conditions. There are a number of other conditions that have to be considered. Radiation effects on human beings may be more or less significant depending upon many factors. For example, there is increasing evidence that irreversible genetic damage may result from exposure of the gonads to any amount of radiation. All such exposure is cumulative. This implies that an exposure that may not produce any harm to the individual himself, may be passed down through the genetic chain to the descendants of this individual. One cannot neglect the possibility that such damage may occur.

I should point out rather quickly that the importance of this problem has been very evident to the National Committee and the International Commission for at least the past 10 years. The problem was clearly recognized by the NCRP in 1946 when it established a new subcommittee on permissible radiation exposure and included 3 geneticists in its membership. In its final report, issued as NBS Handbook 59, there was frequent mention of the problem, although it was felt then that there was insufficient evidence to warrant the establishment of further quantitative limitations on exposure, for purely genetic reasons.

In 1952 the International Commission on Radiological Protection met in Stockholm with a number of genetricists for the specific purpose of considering the genetic problem in relation to the possible exposure of a much larger fraction of the population than had theretofore seemed reasonable. Recognition of the potential hazards of the new nuclear age had been forced upon us.

The impact of radiation exposure on a large homogeneous population group—a few hundred thousand persons—was considered from the point of view of the resultant genetic burden. On the basis of the premises then accepted, the maximum allowable per capita exposure averaged over the population group ranged, from about 3 to 20 rems per person. An average of about 10 rems in addition to background appeared to be a reasonable compromise, but no specific value was officially adopted. One reason for not being specific was the uncertain state of our knowledge of human genetics, and the widespread of opinion among the several geneticists present. Another reason was the belief that the situation would not become sufficiently critical or dangerous within the next 5 or 10 years to warrant the introduction of further limitations on radiation exposure. It should be remarked here that there are still a number of qualified persons who share this belief.

In March of this year the ICRP again took up the genetic question. Again opinion was somewhat divided, but there was clear recognition of substantial improvement in our genetic knowledge—at least of animal genetics. In a very carefully guarded statement they said that "Until general agreement is reached, it is prudent to limit the dose of radiation received by the gametes from all sources additional to the natural background to an amount of the order of the natural bacground in presently inhabited portions of the earth." This would be an amount of the order of 3 to 4 rems in 30 years or roughly 0.1 rem per year. It was further recommended that for radiation workers the exposure be limited to 50 rems accumulated during the employment period up to age 30. If one considers employment of about 10 years, up to age 30, as about average, this would mean an average of 5 rems per year as compared with 15 rems per year, the level in use for the past decade.

Very similar figures were proposed by the National Academy of Sciences in its report issued in June.

In September of this year the National Committee on Radiation Protection met to consider what steps it should take in interpreting these various recommendations for practical use in the radiation field. This was undertaken with some degree of urgency since the National Committee has, for many years, been looked to for the basic recommendations on radiation safety standards in this country. In interpreting the recommendations of the ICRP, it was deemed necessary to introduce numerous qualifications in order to permit reasonable uses of radiation, while at the same time providing reasonable protection not only to the individual but to future generations.

Before going into the details of the NCRP recommendations it should be mentioned that together with genetic considerations, attention was given to the possible effect of radiation exposure upon the average expected life span. Here again, on the basis of animal experiments as well as some limited human data,

there is increasing evidence that either chronic or acute exposure of the whole body to radiation may statistically shorten one's life expectancy. This shortening of life span may amount to as much as 1½ percent per 100 rems of whole body exposure. For partial body exposure the effect would be only a fraction of that for whole body exposure.

Well, these facts, if facts they be, are not such that much comfort can be derived from them. But, they should be considered in proper perspective, and in relation to the many other complicatetd facets that may influence our lives in much the same way.

The National Committee on Radiation Protection felt it was essential to minimize these additional risks—and to some degree controllable—that may be associated with the use of radiation. To this end, it is now proposing a general lowering of the maximum permissible exposure levels for both radiation workers, and, for the general population. These changes are patterned after the 1956 recommendations of the ICRP. Without going into great detail, the new recommendations that are being considered, will be outlined.

First we have defined a controlled area as one under the supervision of a radiation safety officer and one in which personnel can be exposed to radiation or radioactive material. Any person working in a controlled area is a radiation worker.

A summary of the maximum permissible accumulated dose for radiation workers is as follows: The maximum weekly limit for whole body exposure will remain at 0.3 rem per week but will be subject to further limitations. For example there will be a limitation according to age—this is primarily for genetic reasons. Thus:

Up to age 30 the limit will be 50 rems.
Up to age 40 the limit will be 100 rems.
Up to age 50 the limit will be 150 rems.
Up to age 60 the limit will be 200 rems.
Up to age 70 the limit wil be 250 rems.

For design purposes, or for that matter for all practical purposes, these figures indicate that an average exposure of 5 rems per year may be regarded as permissible. On the other hand, the average may be taken over 10 years, provided the decade limits are not exceeded.

Most of the rules given in Handbook 59 will still apply but some will be modified to comply with the average yearly limitations of 5 rems to the blood forming organs, gonads and lens of the eyes, and to a limitation of 10 rems to the skin.

The rule allowing double exposure over age 45 is no longer necessary, but on the other hand, for persons over that age having no radiation history, the weekly limit of 0.3 rem may be taken indefinitely.

Let us consider next the problem in uncontrolled areas. Here we have the situation wherein persons may be subject to radiation without their knowledge or permission. If for no reason other than ethics, their exposure should be substantially less than for a radiation worker. For such persons, the important consideration is their *average* exposure—that is the exposure per individual averaged over the whole population. Thus the exposure of one person may be very much higher than this average, while the exposure of another may be very much lower. This, incidentally, is one of the hardest points to get across to the public. They hear some number like 10 rems bandied about as an average exposure—then they get a dental X-ray which someone says is larger than 10 rems and they think 'they've had it."

Averaging should be done for the population group in which crossbreeding may be expected. While at the moment it is not feasible to determine this average exposure with any reasonable accuracy, the adoption of some figure is necessary for planning purposes.

For the foreseeable future, it may be assumed that the integrated exposure of all radiation workers will be small compared with the integrated exposure of the whole population. Furthermore, persons nonoccupationally exposed in the immediate vicinity of radiation sources constitute only a small portion of the whole population. Therefore, if this latter group is allowed a maximum yearly exposure of 0.5 rem per year, it is not likely that the average per capita exposure to manmade radiations would exceed 6 or 7 rem up to age 30. This, added to the background radiation of 4 rem and medical exposure of 3 rem will make an overall average exposure of 14 rem.

The new recommendations will permit some latitude in the designation of controlled and uncontrolled areas. Within an installation, any space may be designated as a controlled area, and the permissible occupational levels used therein. But, the area and the employees must then be monitored. This leaves to the employee the decision as to whether or not to work there. Matters of economics and employee relations will dictate the decision as to designation of controlled areas.

Permissible radiation levels for internal emitters will conform to the general principles that I have just outlined. Where the critical organ is (*a*) the gonads, (*b*) the whole body, or (*c*) the blood-forming organs, the maximum permissible concentrations for air and water will be one-third the present values specified for radiation workers. For persons outside controlled areas, the maximum permissible concentrations should be further reduced by a factor of 10. Where single organs are regarded as the critical organ, the present maximum permissible concentrations will continue.

Let us return for a few moments to further emphasize the meaning of this average exposure—this figure of 10 rem that has been so thoroughly misunderstood and misused. The genetic limitation on radiation exposure depends upon the total dose to the population—not the dose to any individual. Thus, for every million persons, we will allow in addition to background exposure, a total dose of 10 million rem in their first 30 years, or 14 million rem including background. This million persons includes radiation workers, doctors, dentists, and all other persons whether they receive radiation or not.

Let us see how this 14 million rem is used up. First take medical exposures—according to present practice, this will use up 5 million rem. Next take radiation workers, which may be estimated as not more than one-third percent of the people, or 3,000 per million population. They may receive an average exposure of 50 rem up to age 30—this would use up one-fourth million rem.

Persons living around radiation areas, would not reasonably be expected to exceed 1 percent of the population at the moment. Their radiation allowance is only one-tenth that of radiation workers, or 5 rem in 30 years—this uses up only another quarter million rem. Present background radiation to which all persons are exposed is of the order of 4 rem in 30 years—this will use up 4 million rem.

These figures add up as follows:

	Million rems
Background (now)	4
Medical	5
Occupational	¼
Around plants	¼
Total	9½

Since we can accept a total of 14 million rem per million persons, this leaves a balance—you might say, a reserve—of 4½ million rem, or about half again as much as we are already using. Some of this reserve may eventually go into increases in medical exposure, increase in fallout radiation, increases in atomic power operations, and so on. The way in which we distribute our use of this reserve is a matter to be worked out as time marches on.

So much for the new recommendations of the NCRP.

Now at this point let us think a little about what we have done. Of course it is clear that over a period of many years we have set physical limits to the radiation exposure that man may be allowed to accept. It is also clear that there is an almost total lack of direct experience on the effects of radiation on man. There is a wealth of indirect experience.

Also—and this is a most impressive fact—there are virtually no cases where persons subjected to any of the permissible exposures of radiation have evidenced any detectable harm to themselves.

Let us pause a moment to consider this most unusual situation which has almost no parallel in industrial hygiene. In the well-known situation with silicosis, there was clear evidence as to cause and effect, and positive steps could be taken to minimize its incidence. Similar to radiation, in a sense, is the fact that the disease might first show itself many years after the exposure to silica dust occurred. However, and differing from radiation, once the disease has developed there is a positive relationship to its cause; this is the case with most industrial toxic agents.

One of the most important—if not the most important—aspects of radiation injury is the absence of a clear and definable relationship between the exposure

and the end result. Many of the manifestations of disease that can be ascribed to radiation exposure can equally well develop in persons who have absolutely no radiation exposure history. Considering this, together with the fact that radiation exposure does not excite any of our ordinary sensory organs, makes it loom as a hazard quite distinct from all others. It is primarily for these reasons that such an enormous effort has been expended over the past 30 years on matters of radiation protection. It is surely why, with this particular hazard, we are today relatively so much further ahead than we might be with any other hazard having such a short history. It is the reason why we are doing so much to prevent something from ever happening.

There are perhaps other reasons which exist even though we may not ordinarily think of them as such.

I am reminded of an incident that occurred at a scientific meeting a few years ago. In the course of the discussion of a paper on radiation protection, I was taken to task for having used the phrase, "the science and philosophy of radiation protection." The discussant insisted that the radiation protection problem was straightforward, scientific and clean cut and that there was no argument as to permissible exposure levels and such. I can think of nothing further from the truth, and nearly everything that I've said this evening will bear me out.

The basic problem is even more complicated than just science and philosophy. Here I must tread lightly.

Today, as we consider the total problem of radiation exposure, I feel certain that we are forced to consider not only the philosophical and scientific aspects but also the aspects of morality. I'm not sure where one begins or the other ends.

Consider the most beneficial use of radiation that we can think of—the diagnosis and treatment of disease. No one can question the enormously important benefits that radiation offers in improving our health. To deny ourselves this tool i sto take a step back toward the dark ages. Yet, as we now know, it carries some element of risk—not necessarily to ourselves, but to some unknown, unborn person at some unknown time in the future. How can we balance the choice between our own health—or possibly even our own survival—between this and that unidentifiable life of the future. I suspect the answer is clear, but can we be sure?

For the present, we must preserve our sense of proportion. Through misunderstanding and many confusing public statements, the public does not know what to do. This is becoming more evident daily, as we hear of people refusing to have chest X-rays, or dental examinations. There is no future for that unborn child, if first we die of tuberculosis or infection. Here is where our sense of proportion enters.

For the radiologist or physician or dentist, it is essential that he know more about matters of protection. It is essential that he be trained to perform the necessary examination with the very minimum of exposure to the patient. It is essential that he have equipment designed to minimize or eliminate exposure that serves no useful purpose. It is essential that he know the dose that he administers—at least within some reasonable limits. If he knows this he will almost surely become aware of the protection problem.

For the individual—the prospective patient—it is essential that he place confidence in the physician. The ordinary individual cannot exercise judgment as to the need for radiation diagnosis any more than he can as to the usefulness of a particular prescription. He can, however, avoid unnecessary radiation by not "shopping around for better X-rays", by not using such foolish things as shoe-fitting X-ray machines, and by not bringing unnecessary radioactive devices into his home. Let him keep his sense of proportion.

Let us take the genetic problem. Let us assume that the geneticist is correct in predicting that if we expose the population to an average per capita dose of X rem, we will produce Y genetic deaths at some time within the next Z generations where Z may be any number up to, say, 50. (This is of the order of 1000 or 1500 years.) Let us note that these deaths will be in such forms as failure to conceive, still-births, miscarriages, death below the average lifetime and so on. Let us also note that few if any of these deaths will ever be individually and causatively related to some specific earlier genetic damage caused by radiation.

On the other side of the ledger, let us note that through the use of radiation today we may be able to better our lives either as to material things or as to health.

But even here—strange to say—the problem is complicated by our enormous improvement in health. Many who have faced the problem will question the wisdom of prolonging life to the point of so greatly increasing the number of people in the state of senility. Others will question the wisdom of prolonging,

in misery, the lives of those unfortunates for whom there is no hope in living. The answers to these problems are largely matters of ethics and morality. Of course it must be admitted that through overexposure to radiation we may well augment rather then decrease these numbers.

In any case, with all our knowledge today, we are still dealing with a large number of imponderables. Are we to be morally charged with murder if through our judgment today we allow—or cause—these genetic deaths of the future? Can we leave to the future generations the problem of somehow adjusting themselves to an environment of higher radiation levels? Will the future race be better off or worse off with whatever changes may take place in it? The answer here may lie in whether or not this future race, having knowledge of itself, will consider that he has reached perfection—as apparently we now consider ourselves to have done. This is a matter of opinion.

We pride ourselves today on our greatly increased stature developed over the past few hundred years. For what purpose? It just necessitates a bigger foxhole to keep from being shot by the other guy. A genetic improvement? I sometimes think—facetiously, I'll admit—that we may be in more genetic danger today from automobiles and comic books than from radiation.

But, laying all of these diversions aside, I think our course today is relatively clear. *We must minimize our exposure to radiation. We must maximize the benefits it offers to our health and our material well-being.* These two aims are mutually contradictory as far as we know today. Radiation protection is not only a matter for science. It is a problem of philosophy, and morality, and the utmost wisdom. What is the answer? I don't know. No one does.

(Mr. Taylor's statement—continued.)

I would like at the outset to correct the general impression that radiation hazard is a new problem. It is not. The problem of radiation protection has been under continuous study for nearly 30 years and the setting of permissible dose levels has kept apace with our knowledge and the seriousness of the problem. The present is no exception.

In 1928 the International Commission on Radiological Units and Measurements established the basic radiation units necessary to put protection standards on a quantitative basis. They have revised the units and concepts as necessary to cope with the rapidly changing problems.

EXHIBIT 12, ICRU HISTORY

October 1956

1. FORMATION

The ICRU was formed in 1925 under the auspices of the First International Congress of Radiology, then meeting in London. The single factor having the most bearing on the formation of this Commission was the absence of any units of radiation dosage for use in therapeutic application of radium and X-rays. Up to that time, several units had been proposed and were in use in various countries but there was no international acceptance of anyone of them.

2. MODE OF OPERATION AND HISTORY

In its initial formation, the ICRU consisted of 2 representatives from each of the countries participating in the congresses of radiology. Of these 2 members, 1 was expected to be a physicist and 1 a radiologist. As a matter of fact, about three-quarters of the members were primarily radiologists. Meetings of the ICRU were held during the International Congress. The continuity of the Commission and the arrangement of meetings, agenda, etc., were in the hands of a secretary selected from among the Commission members. The meetings of the Commission were presided over by 1 or 2 honorary chairmen who were usually people of substantial scientific or radiological reputation from the country in which the meeting was held. Occasionally there were also honorary secretaries having no defined responsibilities. In general, these honorary positions were filled by persons having little or no contact with the radiological field and hence were honorary in the strictest sense of the word.

Since there were of the order of 50 countries participating in each International Congress, the rules of the Commission permitted as many as 100 members. As a matter of fact, many countries made no attempt to designate members and the largest number meeting at any one time was 41. With such a large membership, it was extremely difficult to carry out the Commission's work. As

a matter of fact, it usually developed that some 8 to 10 persons carried the load. On the other hand, many countries felt they should have a voice in the matter, with the result that there was an enormous amount of useless discussion at each of the meetings.

Formal minutes of the meetings were not kept. It was considered that the report released by the Commission constituted its findings as well as its minutes.

1925

At the first meeting of the ICRU in London in 1925, some tentative recommendations were made with the idea that they would be considered for action at the next meeting in 1928, at which the full membership would be present.

1928

The second meeting of the ICRU was held in Stockholm in 1928 at which time there were about 40 members present. At this meeting, the Commission adopted the definition of the unit of X-ray dose known as the roentgen. This was an extremely important step forward and for the first time it was made possible to measure radiation in all countries in terms of the same unit. This unit has continued in use to the present time with only minor modifications.

1931

The third meeting of the ICRU was held in Paris in 1931 at which time 39 members were present. Between these meetings, international comparisons of X-ray standards were carried out, one in 1928 by Behnken using a portable thimble chamber, and one in 1931 by Taylor using a portable primary standard. As a result of these intercomparisons, the ICRU in 1931 made some specific recommendations regarding the general characteristics of primary X-ray standards and of the radiation quality ranges over which these standards were to be used. This then marked the first time that there was substantial agreement regarding the basic characteristics of primary radiation standards.

Beginning in 1931, in addition to the members designated by the member countries of the Congress, the Commission also included in its membership representatives designated by each of the recognized national laboratories. At the time, this included the national laboratories of England, Germany, Sweden, and the United States.

At the same time, it became evident that the large size of the ICRU made its deliberations unwieldy. It was therefore proposed that the continuity of program and the direction of the technical discussions be placed in the hands of a small group known as the executive subcommittee. This arrangement was put into effect for the following meeting.

1934

The fourth meeting was held in Zurich in 1934, and was preceded by an informal meeting of the executive subcommittee, then consisting of five persons plus a secretary. At this meeting, it was agreed that the affairs would be managed by the executive subcommittee, with the secretary of the executive subcommittee responsible for the records and continuity between congresses. By this mechanism, the essential technical agreements were reached by the executive subcommittee, and the meeting with the total membership of 33 was mainly for the purpose of accepting and ratifying the previously developed recommendations.

1937

The fifth meeting of the ICRU was held in Chicago in 1937, with 41 members attending. Again at this meeting, the executive subcommittee was in full operation and the affairs were conducted expeditiously. There were no important units recommendations made as a result of the 1934 and 1937 meetings other than those relating to some details in the definition of the roentgen. There was developed at this time the first pattern for a more adequate description of radiation treatment conditions. This was designed to take into consideration all of the many factors necessary for a description of a radiation treatment. These treatment recording recommendations have been continued since that time but have undergone some modification at almost every meeting of the Commission.

Fifteen years lapsed before the next meeting, during which time World War II had been in progress, and many of the original members of the Commission had

either died or been killed. During this interim period Taylor, as secretary of the Commission, had kept abreast of developments in the field preparatory to reviving the Commission's operations.

In reorganizing the Commission, it seemed advisable to change its basis of membership selection in order to avoid the handicap of working with such large numbers. In advance of the fifth congress, discussions were held between L. S. Taylor and W. V. Mayneord and it was agreed that a membership of about 12 would be desirable. With this number, it would no longer be necessary to have an executive subcommittee. This suggestion was put to the past president of the fourth congress and the incoming president of the fifth congress, and was tentatively accepted by them subject to later approval by the International Executive Committee of the Congress. Approval was obtained during the 1950 congress in London.

1950

The reorganized Commission held its sixth meeting in London in 1950. At this meeting a set of rules was developed governing the membership and the work of the ICRU. The rules limited the membership of the Commission to a chairman and 12 additional members, selected for their recognized technical ability without regard to nationality. They also insured a reasonable turnover in membership, yet at the same time provided for adequate continuity of membership.

In its 1950 recommendations, the ICRU recognized for the first time the need for absolute measurements of radiation based on calorimetry or other fundamental techniques. It recognized further that the Commission was not in a position at that time to make any specific recommendations but the way was prepared for introducing improvements at a later time. There was also developed a more completed section on the specification for the description of X-ray treatments.

For the year or 2 prior to the 1950 meeting, the American and British Units Committees had been very active in the development of the concepts of energy measurements as applied to radiological problems. These were widely circulated well in advance of the meetings with the result that at the 1950 meetings, it was relatively easy to bring about substantial agreement between the different viewpoints prevailing. This advance action paved the way for the acceptance of the new energy unit for dose proposed later by the Americans and British.

1952

In 1952, a joint meeting was held in Stockholm between the ICRU, the ICRP, and the UNESCO Joint Committee in Radiobiology. This meeting was primarily for the purpose of discussing the genetic aspects of radiation. While it was agreed that no specific recommendations would be made as a result of these meetings, it is interesting to note that the general findings were substantially the same as those made in 1956 by the ICRP and by the National Academy of Sciences.

1953

The seventh meeting of the ICRU was held in Copenhagen in 1953 with 12 members attending. The most important outcome of this meeting was the introduction of a new basic unit for the measurement of radiation dose. This unit, known as the rad, was designed to place the measurement of dose on the basis of first principles. The reason for this was related to the fact that we were using energies very much higher than was ever dreamed of in the thirties, and for which the roentgen is not always the most suitable unit of measurement. It was clearly recognized during these meetings that much more information needed to be provided before the rad could be regarded as a practical unit. However, between 1953 and 1956, its attractions became evident and it has begun to appear regularly in the radiological literature.

The Commission established two subcommittees to provide more concentrated studies in the fields of X-ray standard and standards of radioactivity. Dr. W. J. Oosterkamp (Netherlands) served as chairman of the Subcommittee on X-ray Standards, and Dr. B. Rajewsky (Germany) as chairman of the Subcommittee on Standards of Radioactivity.

During the 1953 meetings, the Commission held its first symposium at which invited papers were presented on current work in radiation units and measurements. This provided an opportunity to discuss at open meetings the work being done in various countries and the problems that require further investigation.

1955

In 1955, an informal meeting of the ICRU was held in Geneva during the International Conference on the Peaceful Uses of Atomic Energy. This was attended by those members present at the conference; and was mainly in preparation for the formal meeting to be held the following year.

1956

The eighth meeting of the ICRU was held in Geneva in the spring of 1956. This marked the first time that the Commission had met separately from the meetings of its parent organization—the International Congress of Radiology. Meetings were held jointly with the ICRP and extended over a period of 12 days.

Another departure at these meetings was the fact that they were held with the assistance of the World Health Organization. This resulted from contacts made during the preceding few months, when the WHO had indicated its need for technical advice in the field of radiation units and protection. During the course of the meetings, the Commission accepted the invitation of WHO to enter into an official relationship as a nongovernmental participating organization. As a result of this relationship, the ICRU is now recognized by the World Health Organization as its body of technical advisers in the field of radiological units and measurements.

The meetings were attended by the 10 members and the chairman of the main Commission; 11 subcommittee members and 5 subcommittee consultants were also in attendance.

The report of the ICRU developed during the 1956 meetings represents the most complete effort thus far. In addition to some degree of clarification of the different units used in measuring radiation dose, the report will include for the first time a large body of technical data. It also will include extensive discussions and instructions regarding the problems met in introducing the new energy units into medical and biological practice.

It was also agreed that some interim secondary standards of radiation measurement should be developed and made available to any countries requiring calibration of its equipment. The National Bureau of Standards (United States) agreed to undertake the responsibility for the development and construction of this equipment.

The committee structure of the Commission was reorganized and enlarged, and patterned very closely after that developed recently by the National Committee on Radiation Protection and Measurements in the United States. As a result, there are now the following four committees:

Committee I: Standards and Measurement of Radioactivity for Radiological Use. Chairman: W. E. Perry, United Kingdom.

Committee II: Standards and Measurement of Radiological Exposure Dose. Chairman: H. O. Wyckoff, United States.

Committee III: Measurement of Absorbed Dose and Clinical Dosimetry. Chairman: L. H. Gray, United Kingdom.

Committee IV: Standard Methods of Measurement of Characteristic Data of Radiological Equipment and materials. Chairman: B. Combée, Netherlands.

In order to better describe the Commission's scope of activities, it's name was changed at this time to International Commission on Radiological Units and Measurements (ICRU).

During the meetings, 2 half-day symposiums were held for the purpose of presenting and discussing 17 reports on specialized problems in the field of radiation units and measurements. The symposiums were arranged by the ICRU, and through the assistance of the World Health Organization, were held in the U. N. buildings. They were attended by some 75 persons including members of the ICRP and its subcommittees.

For a period of 3½ days following the commission meetings, selected members of the ICRU met with a WHO study group to consider on a worldwide basis how the recommendations of the ICRU might better be implemented. As a result of this study, the WHO will take active steps to disseminate on a worldwide basis the recommendations developed by the ICRU.

1956

An informal meeting of the ICRU was held in Mexico City in the summer of 1956 during the Seventh International Congress of Radiology. Seven members

who were in attendance at the congress met to work on some of the phraseology of the report which had been developed in Geneva.

At the time of writing, preparations are going forward for a joint meeting of the ICRU and ICRP to be held in New York October 31 to November 7, for the purpose of discussing a number of problems to be studied for the U. N. Scientific Committee on the Effects of Atomic Radiation.

Listed below are the formal meetings of the ICRU held since its inception, the number of members in attendance, and the commission officers. (The officers listed were in office at the time of meeting. Terms of new officers begin after confirmation of their election during the international congress, and continue for a 3-year period corresponding to the interval between congresses. Honorary chairmen are not listed.)

Date and place of meeting	Members present	Officers
1925, London	(?)	E. A. Owen (United Kingdom), secretary.
1928, Stockholm	40	Do.
1931, Paris	39	Do.
1934, Zurich	33	Do.
1937, Chicago	41	L. S. Taylor (United States), secretary.
1950, London	13	W. V. Mayneord (United Kingdom), chairman; L. S. Taylor (United States), secretary.
1953, Copenhagen	12	Do.
1956, Geneva	[1] 11	L. S. Taylor (United States), chairman; W. J. Oosterkamp (Netherlands), secretary.

[1] Main commission only. 11 subcommittee members and 5 subcommittee consultants were also present.

The Eighth International Congress of Radiology is scheduled to met in Munich in 1959. The next formal meeting of the ICRU has not been scheduled and may be held prior to the congress. It is expected that committees of the ICRU will meet more frequently than the main commission to expedite the completion of their special studies. For the period 1956–59, the membership of the main commission numbers 13, and that of the 4 committees (including consultants) will be approximately 40 to 50. Officers of the main commission for this period are L. S. Taylor (United States), chairman; L. H. Gray (United Kingdom), vice chairman; H. O. Wyckoff (United States), secretary.

(Mr. Taylor's statement—continued.)

Beginning in 1928, the International Commission on Radiological Protection has set standards and protection procedures on an international basis.

Exhibit 13. ICRP History

October 1956

1. Formation

The ICRP was formed in 1928 under the auspices of the Second International Congress of Radiology then meeting in Stockholm. The formation of an international protection committee had been discussed by the first congress in 1925 but no active steps had been taken at that time toward this end.

During the second congress, plans for organizing an international protection committee were developed by G. W. C. Kaye and Stanley Melville (Great Britain). and L. S. Taylor (United States). Dr. Gustav Grossman (Germany) and Dr. Rolf Sievert (Sweden) were brought into the discussions and plans were completed for the organization of a committee. Their proposal and organization plan were presented to the second international congress and were approved. The committee was named the International X-Ray and Radium Protection Committee, and its membership consisted of the five individuals who planned the organization.

2. Mode of Operation and History

Because of the experience of the ICRU with its large and unwieldy membership, the committee decided at the outset to keep its membership as small as possible. It also decided to include in its membership only people who were working actively in the general field of radiation protection. For this reason, the initial committee consisted of only five persons. This was enlarged for the

next congress by adding Dr. Iser Solomon of France and Dr. Pugno-Vanoni of Italy.

The ICRP, because of its small size, was operated much more informally than the ICRU. The chairman from 1928 through 1937 was Dr. G. W. Kaye, then of the National Physical Laboratory, and the honorary chairman Dr. Stanley Melville. It might be remarked (with some interest in view of later events) that at the time of its formation the problem of radiation protection was not considered to be as important or as serious as that of radiation units. Members of the ICRP felt that the problem would grow and sought to be prepared.

1928

The committee held its initial meeting in 1928 for the purpose of adopting some interim protection regulations. Until that time, the only clearly formulated recommendations were those prepared a few years earlier by the British committee. These were used as a basis for discussion. The first recommendations of the committee were very similar to the early British proposals, and until 1950 its recommendations were patterned around these early British recommendations.

1931

The second meeting of the committee took place in Paris in 1931 and was attended by all seven members. At this meeting, there was some discussion of the possibility of introducing so-called tolerance levels of radiation for radiation workers. This was recognized as desirable, but with very little evidence to go on, no specific recommendations were made.

1934

The third meeting took place in Zurich in 1934 and was again attended by all seven members. This meeting was notable because there was established for the first time a permissible level of radiation exposure. This was related to the newly established unit of X-ray dose—the roentgen. The level then set was 0.2 roentgens per day. (It might be noted that the year following this, the National Committee on Radiation Protection in the United States recommended a lower level of 0.1 roentgen per day.)

1937

The fourth meeting was held in Chicago in 1937 with the same seven members attending.

Throughout the period 1928 through 1937, the main work of the committee consisted of gradually enlarging and extending the recommendations originally developed at its first meeting. Until then, the main item of the protection recommendations was the specification of the thicknesses of barriers of various materials that should be interposed between a source and an individual in order to assure adequate protection. Prior to the establishment of the permissible dose in 1934, these barrier thicknesses had been somewhat arbitrary. In 1934 and again in 1937, the relationship of the barrier thickness to the actual dose in roentgens was clarified and was put on a sound quantitative basis.

Following the deaths of both the chairman and the honorary chairman, L. S. Taylor acted as secretary for the committee until its next meeting which was not to occur until 1950.

Under circumstances similar to those of the ICRU, the ICRP was reorganized in 1950 on a different basis from that which prevailed before the war. By that time, the questions of radiation protection had assumed far greater importance than it had earlier. This, of course, was due to the advent of atomic energy. The Committee was enlarged in size to 12 members in order to better deal with the problems facing it. The new membership was made up of individuals having recognized standing in the field without regard to nationality, and its operating rules were made the same as those of the ICRU. At this time, its name was changed to International Commission on Radiological Protection.

1950

The ICRP held its fifth meeting in London in 1950, attended by 9 members and a chairman. Between 1946 and 1950, a large body of protection information had been prepared by the NCRP in the United States, having to do with

exposure of the whole body to radiation from both external and internal sources. The NCRP had also developed considerably more details in the general field of X-ray protection. This large background of information was used as a basis for discussions of the ICRP which resulted in the development of its 1950 report. It should be mentioned that an extensive interchange of this information had previously been accomplished through the medium of the tripartite conferences between the United States, Canada, and England. The results of these conferences were in turn based to a considerable extent on data developed during the Manhattan District days.

With the availability of this new information, the ICRP lowered the maximum permissible dose for radiation workers from 0.2 r/day (in use since 1934) to 0.3 r/week. The report also included for the first time maximum permissible concentrations in the body of approximately ten radioactive isotopes.

Because of the very large task confronting it, the ICRP established subcommittees to deal with special phases of the radiation protection problem, their general structure following that developed a few years earlier by the NCRP. This arrangement has greatly facilitated the development and presentation of information.

1952

An interim meeting of the ICRP was held in Stockholm in 1952, with the ICRU and the UNESCO Joint Committee on Radiobiology. At this time, the major subject under consideration was the possible genetic effects of radiation. The meeting was attended by a number of geneticists from several countries. At this time, it was recognized that the genetic effects of radiation were becoming better understood and should be taken into consideration. Figures were discussed for an average per capita dose for a large population. However, because there was very little agreement between the geneticists themselves, and because of the meager information available on this question, it was decided not to make any specific recommendations. (It is interesting to note, however, that the recent recommendations made on this question in 1956 by the ICRP and by the National Academy of Sciences and other groups give approximately the same range of figures as those discussed at the Stockholm meeting in 1952.)

1953

The sixth meeting of the ICRP was held in Copenhagen in 1953. This was a joint meeting with the ICRU and was held during the week preceding the opening of the International Congress. Most of the representatives on the subcommittees also met.

The report of the commission as developed during these meetings marked a radical departure from all others. Its total size was 92 pages and it included a great amount of detail never before agreed upon on an international basis.

The main body of the report consisted essentially of the reports of its five subcommittees:

1. Permissible Dose for External Radiation
2. Permissible Dose for Internal Radiation
3. Protection Against X-rays Generated at Potentials Up to Three Million Volts
4. Protection Against X-Rays Above Three Million Volts, Beta Rays, Gamma Rays, and Heavy Particles Including Neutrons and Protons
5. Handling and Disposal of Radioactive Isotopes

The recommendations on permissible dose from external radiation were somewhat broadened over those previously made, but the basic permissible exposure level of 0.3 r/week was reaffirmed.

Subcommittee 2 gave the maximum permissible concentrations of radioactive materials in the body, air, and water for nearly 100 radioactive isotopes, and included a large body of reference material.

Subcommittee 3 produced a very detailed report applying to both medical and industrial radiology, and included recommendations regarding radiation levels from special devices such as television receivers.

Subcommittees 4 and 5 issued brief reports; much of the material in their areas was still in an unsatisfactory state at that time.

With the development of this detailed report, a new problem arose. Previously the reports had been relatively short and could be published as a few pages in any of the technical journals. However, this report was too large to be published in this manner, and for some time there was uncertainty as to whether

or not it could be published in its entirety. Eventually it was published as a supplement to the British Journal of Radiology. This had to be underwritten, and for this purpose, some funds were obtained from the British electrical industry.

Further difficulty arose because of the expense of carrying out the duties of the secretariat of the ICRP. This expense was borne first by the National Physical Laboratory and then by the British Medical Research Council. All other expenses of the operation were handled on a voluntary basis with the parent organization of the individual members bearing their expenses.

1956

The seventh meeting of the ICRP took place in Geneva in March 1956, and was held jointly with the ICRU over a period of 12 days.

The report developed in 1953 was not changed in principle. However, greater emphasis was placed on the earlier cautions to keep radiation exposure levels as low as possible regardless of the weekly limits permitted. It was specifically recommended that the accumulated exposure of occupational workers be kept below 50 rem up to age 30. The compilation of permissible concentrations of radioactive isotopes in the body and in the air and water was considerably enlarged to include nearly 200 radioactive isotopes. A new subcommittee was established, in place of the former Subcommittee V, to deal with the problems of radioactive waste disposal.

During these meetings, the Commissions' affiliation with the World Health Organization as a nongovernmental participating organization in the WHO program was ratified. This affiliation came about as a result of contacts made in the fall of 1955 between the World Health Organization and the ICRP with a view to determining if the latter would participate in the WHO activities. The matter was taken up with the members by correspondence, and it was agreed that the ICRP should give its assistance to WHO. Under the arrangement made, the WHO will not influence the operation of the ICRP but will look to it for guidance in matters of radiation protection.

During the meetings, the relationships between the ICRP and the ICRU were more firmly established. They have always operated as separate commissions but since their inception they have always met at the same time and have maintained close collaboration. There has also been a certain degree of overlap in membership. There is now a clear statement of policy that the two Commissions will work together and consult one another on matters of common interest.

There were also extensive discussions regarding the possibility of forming an international protection organization, to be privately financed so as to avoid any nationalistic or political influence. If such an organization were formed, the ICRU and ICRP would be blended into the one organization. No attempt was made to work out the details of such an arrangement, but no difficulties in doing this are foreseen.

It was agreed that if such an organization were established, it should have some semiofficial ties with WHO and U. N. without becoming a part of their organization or subject to their direct control. It is felt that one of the strongest points of both Commissions is their freedom to select membership without regard to matters of national policy or other such influences.

Following the meetings of the ICRP in Geneva, a 3½ day joint session was held by some of its members, some members of the ICRU, and representatives from the WHO. The main purpose of this meeting was to outline to WHO the nature of the ICRP work and to point out ways in which WHO might assist in the worldwide implementation of the recommendations of the Commission. A number of specific recommendations were made to WHO and it is believed that they are taking steps to follow these through.

As of the time of writing, the 1956 report of the Commission has not been officially released. There is again the problem of financing the publication costs. In this connection, WHO has offered to indirectly subsidize the publication by guaranteeing the purchase of 500 copies of the report; this will offset the costs to some extent.

Listed below are the formal meetings of the ICRP held since its inception, the number of members in attendance, and the Commission officers. (Officers listed were in office at the time of meeting. Terms of new officers begin after confirmation of their election during the International Congress, and continue for a 3-year period coresponding to the interval between Congresses. Honorary chairmen are not listed.)

Date and place of meeting	Members present	Officers
1928, Stockholm	5	G. W. C. Kaye (United Kingdom), Chairman.
1931, Paris	7	Do.
1934, Zurich	7	Do.
1937, Chicago	7	Do.
1950, London	10	E. Rock-Carling (United Kingdom), Chairman, L. S. Taylor (United States), Secretary.
1953, Copenhagen	11	E. Rock-Carling (United Kingdom), Chairman, W. Binks (United Kingdom), Secretary.
1956, Geneva	[1] 12	Do.

[1] Main Commission only. Subcommittee membership totaled approximately 50: a substantial number of these were in attendance.

The Eighth International Congress of Radiology is scheduled to meet in Munich in 1959. The next formal meeting of the ICRP has not been scheduled and may be held prior to the Congress. For the period 1956–59, the officers of the main Commission are R. Sievert (Sweden), Chairman; G. Failla (United States), Vice Chairman; W. Binks (United Kingdom), Secretary.

(Mr. Taylor's statement—continued.)

The National Committee on Radiation Protection and Measurements beginning in 1929 has done the same for the United States on a continuing basis.

Exhibit 14. NCRP History

1929–46

1. Formation

The roots of the National Committee on Radiation Protection and Measurements go back to 1928 and are intimately related to the formation of the International Commission on Radiological Protection in July of that year. With the possibility in mind of forming an international organization on radiological protection, the Second International Congress of Radiology, before meeting in Stockholm in July 1928, invited several countries to send representatives to the Congress for the purpose of discussing protection problems and possibly preparing some initial X-ray protection recommendations. From the United States, L. S. Taylor was designated as representative of the National Bureau of Standards, and one representative each attended for the American Roentgen Ray Society and the Radiological Society of North America.

When attempts were made to reach agreement between the United States and other countries, serious difficulties arose. Each of our two radiological societies offered different recommendations and each claimed to be the authoritative body. The NBS had no recommendations to offer and was there more by way of an observer. As a result, the recommendations that were in fairly acceptable form, prepared by the British protection committee, were adopted as the first international recommendations. In the process, the United States delegates showed up rather poorly in that agreement could not be reached on who authoritatively represented the views of the United States.

Germany presented a somewhat similar though not quite so serious a situation as had the United States, in that its representatives at the preliminary discussions also could not agree on who carried the necessary authority.

Concurrent with the meetings of the Congress, G. W. C. Kaye and Stanley Melville (Great Britain) and L. S. Taylor (United States) set about to organize a permanent structure for an international organization. After preliminary discussions, during which some general rules of organization were developed, the International Commission on Radiological Protection[1] was organized, the membership consisting of the above-mentioned persons, Dr. Rolf Sievert of Sweden and Dr. Gustav Grossman of Germany. It was agreed by this group that the Commission should be kept small, and that wherever possible, representatives to the Commission should be chosen from national laboratories where such laboratories existed in member countries. This arrangement and the general philosophy of operation of the Commission was approved by the Second International Congress of Radiology before the close of its sessions.

[1] Until 1946, the Commission was called the International X-ray and Radium Protection Committee.

Because of the confusion regarding accredited representation, introduced primarily by the United States but also by Germany and to a lesser extent by France, the chairman of the ICRP, Dr. G. W. C. Kaye, recommended that a single central committee be established within those countries having more than one radiological organization for the purpose of consolidating national recommendations for presentation at the next meeting of the Commission. It was suggested that the members of the ICRP take this up individually with the various groups in their countries.

As the United States representative to the international protection group, it became the responsibility of L. S. Taylor, to convey its recommendations to the various groups involved in this country, to convince them of its soundness, to obtain their approval and suggestions, and to organize a national committee which could deal most effectively with the protection problems faced at that time.

In September 1928, this question was discussed informally with the president of the American Roentgen Ray Society, at its annual meeting in West Baden, Ind. Similar discussions were held with the president of the Radiological Society of North America in December of that year. As a result of these discussions, these organizations agreed to consolidate their protection activities into a single committee. They further recommended that the committee's activities be centralized at the National Bureau of Standards for the following reasons:

(1) It had by that time established a definite long-range program in the general field of radiation protection;

(2) It had the only laboratory in the country as its primary interest the development of radiation-protection data and information;

(3) It had no intersociety or political ties and therefore could be expected to retain an independent position and viewpoint; and

(4) It provided the official United States representative to the International Commission on Radiological Protection.

The two radiological societies each recommended a physicist and a radiologist for membership in the proposed national committee, and the American Medical Association appointed a member to represent its viewpoints. It was also felt that representation of the X-ray equipment manufacturers would be desirable and each of the manufacturers was asked to nominate candidates for this representation. Of the nominations received, the manufacturers then chose two to serve as their representatives.

Thus, early in 1929, the initial organization of the Advisory Committee on X-ray and Radium Protection was established with L. S. Taylor acting as chairman and with the following participating organizations and representatives:

American Roentgen Ray Society: H. K. Pancoast and J. L. Weatherwax
Radiological Society of North America: R. R. Newell and G. Failla
American Medical Association: Francis Carter Wood
X-ray equipment manufacturers: W. D. Coolidge and W. S. Werner
National Bureau of Standards and ICRP: Lauriston S. Taylor

2. HISTORY

The first meeting of the Committee was held in September 1929, during the annual meeting of the American Roentgen Ray Society. As its first objective, the Committee undertook the preparation of recommendations on X-ray protection. These were published on May 16, 1931, as National Bureau of Standards handbook 15.

The next effort was directed toward the preparation of recommendations on radium protection. For this purpose, Dr. L. F. Curtiss was named to the Committee as the NBS representative for radium protection recommendations, and Dr. C. F. Burnam as the representative of the American Radium Society. The first handbook on radium protection, NBS handbook 18, was prepared by Drs. Curtiss, Burnam, Failla, Newell, Weatherwax, and Wood, and was published March 17, 1934.

Soon after the publication of handbook 15 on X-ray protection, very rapid developments were made in the X-ray field; by 1934 or 1935 it was recognized that this handbook would have to be revised. This task was undertaken by the original Committee, except for the replacement of Dr. Pancoast by Dr. Eugene P. Pendergrass as representative of the American Roentgen Ray Society. The revised recommendations were issued in July 1936, as NBS handbook 20.

It might be worth noting that in this handbook, there appeared for the first time the recommendation of a specific permissible exposure level (then called tolerance dose) of radiation that could be allowed for occupational exposure. The figure recommended was 0.1 roentgen per week. This permissible exposure level remained in force for 12 years and was used by the Manhattan District in its operations. It was subsequently changed as a result of NCRP action in about 1948.

The revision of handbook 18 on radium protection was next undertaken and the new handbook (H 23) was issued August 25, 1938.

These two handbooks, H 20 and H 23, were accepted in this country as the primary guides for protection against X-rays and the radiations from radium. As noted above, they were also the primary guides in this field to the Manhattan project.

Through the war years, there was no formal activity by the Advisory Committee. During that time, however, most of the members of the Advisory Committee were drawn into the Manhattan District program and it was largely through their efforts that uniform safety regulations prevailed during that period.

During its early activities, it was customary for the full committee to work together on the development of protection recommendations. When completed, the recommendations were submitted through their respective representatives to the participating organizations for noting and approval. Formal approval was usually given at one of the regular business meetings of the societies. With the NBS as sponsor of the committee, the recommendations were published by the Government Printing Office as National Bureau of Standards handbooks thus receiving the usual NBS editorial processing.

In September 1946, an informal meeting of the Advisory Committee was held to discuss the extensive revision needed in the X-ray protection recommendations, particularly in the upper voltage regions. At this meeting, it was pointed out that protection problems had become too complex to permit their study and solution by the Committee as then constituted. It was recommended that steps be taken to secure the participation in this work of additional groups such as the Manhattan District and United States Public Health Service, military department, etc. This recommendation was presented to Dr. Condon, then Director of NBS, who communicated with the Manhattan District and the Public Health Service on October 8, 1946, inviting their participation through appointment of 2 representatives each (1 psysicist and 1 radiologist). In response to this invitation, in October 1946, Dr. Stafford L. Warren and Dr. K. Z. Morgan were appointed as representatives of the Manhattan District, and the Public Health Service named Dr. Howard L. Andrews and Dr. E. G. Williams.

The first formal postwar meeting of the committee was held on December 4, 1946. In the agenda for this meeting, it was pointed out that new data had become available since the issuance of the recommendations on X-ray protection, and that many new protection problems had arisen with the rapid expansion in the radiation yield (protection against neutrons, multi-million-volt X-rays, radioactive isotopes, etc.). It was suggested that the scope of the work be defined; and that consideration be given to organizing small working groups to deal with each of the problems, their completed reports to be submitted to the committee for approval.

3. ORGANIZATION

Discussions along these lines were held at the December 4, 1946, meeting, and as a result, it was agreed that the committee should be substantially enlarged and reorganized. At the same time, it was felt that the name of the committee should be made more inclusive and it was therefore renamed National Committee on Radiation Protection. The National Bureau of Standards was reaffirmed as the central coordinating agency for the work of the committee; sponsorship by an impartial agency was felt to be particularly advantageous in view of the various types of participating organizations (radiological societies, industry, government, and the possible inclusion of industrial and labor groups).

The general organization and operational procedures outlined below were agreed upon at this meeting, and have been the basis for the continuing operation of the committee:

1. The committee would consist of an executive committee, main committee, and as many subcommittees as necessary to consider the problems that come within the committee's scope.

2. The executive committee would be composed of five members appointed by the chairman and subject to the approval of the main committee. The committee chairman would act as chairman of the executive committee.

3. The main committee would be composed of (1) technically qualified representatives appointed by organizations interested in the scientific and technical aspects of radiation protection, (2) representatives at large whose services are felt to be of special value, appointed by the executive committee and (3) chairmen of subcommittees.

4. The choice, of chairmen and members of subcommittees would not be restricted to members of the main committee but would be based on the particular qualifications needed for the work. (In organizing subcommittee memberships, the following practice has been and still is followed: The subcommittee chairman is selected by the committee chairman with the approval of the executive committee; the subcommittee chairman chooses his working group, makes informal contacts, and submits to the committee chairman his membership selections; the committee chairman issues formal membership invitations to serve on the subcommittees. Additions may be made to the subcommittee membership if particular specialized information is found to be needed, or individuals may be invited to serve as consultants to the group with due acknowledgment of their assistance included in the published recommendations.)

5. The final reports of the subcommittees would be submitted to the executive and main committees for approval. Because of the high degree of success of the NBS handbook series, it was recommended that this mode of publication and distribution to the public be continued.

Because of the reorganization and enlargement of the committee, the chairmanship was thrown open for reconsideration . L. S. Taylor was nominated and approved by vote to continue indefinitely in this capacity.

Discussions were held regarding the organizations that might appropriately be invited to participate and the suggestions made were used as a basis for the subsequent enlargement of the representation on the main committees.

It was agreed to establish the following subcommittees:

1. Permissible external dose
2. Permissible internal dose
3. X-rays up to 2 million volts
4. Heavy ionizing particles (neutrons, protons, and heavier)
5. Electrons, radium, and X-rays above 2 Mev.
6. Radioactive isotopes, fission products, including the handling and disposal
7. Monitoring methods and instruments

With the formulation of these basic philosophies, the committee began its active program. Its accomplishments and growth since its reorganization in 1946 can be seen by the appended list of handbooks published to date, and the appended membership list showing the present representation, subcommittee structure, and complete membership.

Recommendations of NCRP, 1931–55

NBS Handbook No.	Title	Date
15	X-ray protection: Superseded by H-20	May 16, 1931.
18	Radium protection for amounts up to 300 mg.: Superseded by H-23	Mar. 17, 1934.
20	X-ray protection: Superseded by H-41	July 24, 1936.
23	Radium protection: Superseded by H-54	Aug. 25, 1938.
41	X-ray protection up to 2,000,000 volts: Superseded by H-60	Mar. 30, 1949.
42	Safe handling of radioactive isotopes	September 1949.
48	Control and removal of radioactive contamination in laboratories	Dec. 15, 1951.
49	Recommendations for waste disposal of phosphorus 32 and iodine 131 for medical users.	Nov. 2, 1951.
51	Radiological monitoring methods and instruments	Apr. 7, 1952.
52	Maximum permissible amounts of radioisotopes in the human body and maximum permissible concentrations in air and water.	Mar. 20, 1953.
53	Recommendations for the disposal of carbon 14 wastes	Oct. 26, 1953.
54	Protection against radiations from radium, cobalt 60, and cesium 137	Sept. 1, 1954.
55	Protection against betatron-synchrotron radiations up to 100,000,000 electron volts.	Feb. 26, 1954.
56	Safe handling of cadavers containing radioactive isotopes	Oct. 26, 1953.
58	Radioactive-waste disposal in the ocean	Aug. 25, 1954.
59	Permissible dose from external sources of ionizing radiation	Sept. 24, 1954.
60	X-ray protection	Dec. 1, 1955.
61	Regulation of radiation exposure by legislative means	Dec. 9, 1955.

[1] Modification mainly to reflect the new permissible dose levels of January 8, 1957.

(Mr. Taylor's statement—continued.)

Since the war the recommendations of the ICRP have been guided, in a large measure, from those developed by the NCRP and the international recommendations and standards reflect pretty generally the United States standards. This is not surprising when one considers that the shaping of the program and the

chairmanship of some of the committees on the ICRP are in the same hands as of corresponding subcommittees of the NCRP.

EXHIBIT 16. RELATIONSHIP BETWEEN THE WORK OF THE NCRP AND THE INTERNATIONAL COMMISSIONS

OCTOBER 1956.

RELATIONSHIP BETWEEN THE WORK OF THE NCRP AND THE INTERNATIONAL COMMISSIONS

As noted in the foregoing, the NCRP has been a very active continuing organization since its inception in 1929. Also because of the very much greater activity in the radiation field in the United States as compared with most other countries, the NCRP has been able to develop much more detailed information in matters of radiation protection. For this reason, it is not unnatural that there should have been a number of areas in which the general recommendations and philosophies of the NCRP have influenced the international recommendations.

A major example was the adoption by the ICRP in 1950 of the lower maximum permissible exposure levels recommended by the NCRP 2 or 3 years earlier and already in use in this country. The adoption of these levels was also facilitated by the tripartite conferences between England, Canada, and the United States, the results of which were based on the information supplied by the NCRP.

When the ICRP subcommittee structure was first established in 1950, it was patterned fairly closely after that already in use for several years by the NCRP. In fact the chairman selected for subcommittees I and II of the ICRP were the chairman of the corresponding subcommittees of the NCRP. In addition, many of the individuals selected for membership on the other subcommittees of the ICRP were members of the corresponding NCRP subcommittees.

The maximum permissible concentrations of radioactive isotopes in the body, and in air and water, which were included in the 1950 ICRP report, were those developed initially by the NCRP for its Handbook 52, then in the course of preparation.

In the report of the ICRP developed in 1953, the reports by three of the subcommittees (on permissible dose from external and from internal sources of radiation and on X-ray protection) were taken very largely from the corresponding reports developed by the NCRP. In fact, these NCRP reports were used as the basis for consideration of these subjects by the ICRP.

Similar close relationships have existed between the NCRP and the ICRU. It could not be said with fairness that the most recent recommendations of the ICRU reflect dominantly the opinion of any one group, as all of the representatives participated actively in its preparation . On the other hand, the new committee structure of the ICRU is patterned after that which had been adopted by the NCRP a short time previously. With this extension of activities, the ICRU organizational structure now includes the following:

Committee I, Standards and Measurements of Radioactivity for Radiological Use
Committee II, Standards and Measurements of Radiological Exposure Dose
Committee III, Measurement of Absorbed Dose and Clinical Dosimetry
Committee IV, Standard Methods of Measurement of Characteristic Data of Radiological Equipment and Material

Throughout the membership composition of these four committees, there is substantial overlap in both officers and members with the corresponding subcommittees of the NCRP.

(Mr. Taylor's statement—continued.)

The National Committee on Radiation Protection (NCRP) is currently sponsored by the National Bureau of Standards and is made up of representatives of various scientific and technical organizations and governmental departments. In this way, there is close coordination between the committee's activities and those of other interested groups. This applies particularly to the relationships with the AEC with whom there is the closest collaboration. In fact, the Atomic Energy Commission supplies a small allotment of funds to the NCRP for its work. At the same time, the recommendations of the NCRP are made without undue influence on the part of the AEC.

EXHIBIT 17. LIST OF NCRP PARTICIPATING ORGANIZATIONS, SUBCOMMITTEES AND MEMBERS, MEMBERSHIP OF EXECUTIVE COMMITTEE, JULY 1956

Lauriston S. Taylor, chairman
Sarah W. Raskin, secretary

EXECUTIVE COMMITTEE

C. L. Dunham
G. Failla
R. S. Stone
L. S. Taylor
E. G. Williams

MAIN COMMITTEE (AND ORGANIZATION REPRESENTED)

H. L. Andrews, USPHS and subcommitte chairman
E. C. Barnes, American Industrial Hygiene Association
A. C. Blackman, International Association of Government Labor Officials
C. B. Braestrup, subcommittee chairman
J. C. Bugher, representative at large
R. H. Chamberlain, American College of Radiology
W. D. Claus, USAEC
C. L. Dunham, USAEC
T. P. Eberhard, American Radium Society
T. C. Evans, American Roentgen Ray Society
G. Failla, Radiological Society of North America and subcommittee chairman
P. C. Hodges, American Medical Association
H. W. Koch, subcommittee chairman
S. E. Lifton, Colonel, United States Air Force
W. Langham, subcommittee chariman
E. A. Lodmell, Colonel, United States Army
W. B. Mann, subcommittee chairman
G. W. Morgan, subcommittee chairman
K. Z. Morgan, representative at large and subcommittee chairman
R. J. Nelsen, American Dental Association
R. R. Newell, American Roentgen Ray Society
H. M. Parker, subcommittee chairman
E. H. Quimby, American Radium Society and subcommittee chairman
S. W. Raskin, National Bureau of Standards
J. A. Reynolds, National Electrical Manufacturing Association
H. H. Rossi, subcommittee chairman
M. D. Schulz, American College of Radiology
L. S. Skaggs, subcommittee chairman
J. H. Sterner, American Industrial Hygiene Association
R. S. Stone, Radiological Society of North America
I. R. Tabershaw, International Association of Government Labor Officials
L. S. Taylor, National Bureau of Standards
E. D. Trout, National Electrical Manufacturing Association
Shields Warren, representative at large
J. L. Weatherwax, representative at large
E. G. Williams, USPHS
S. F. Williams, Captain United States Navy
H. O. Wyckoff, subcommittee chairman

SUBCOMMITTEE 1. PERMISSIBLE DOSE FROM EXTERNAL SOURCES

G. Failla
A. H. Dowdy
H. Friedell
H. J. Muller
H. M. Parker
K. Stern
R. S. Stone

SUBCOMMITTEE 2. PERMISSIBLE INTERNAL DOSE

K. Z. Morgan, chairman
A. M. Brues
G. Failla
J. G. Hamilton
L. D. Marinelli
H. M. Parker
J. E. Rose
Shields Warren

SUBCOMMITTEE 3. X-RAYS UP TO 2 MILLION VOLTS

H. O. Wyckoff, chairman
C. B. Braestrup
T. P. Eberhard
R. H. Morgan
R. J. Nelsen
R. R. Newell
S. W. Smith
E. D. Trout

SUBCOMMITTEE 4. HEAVY PARTICLES (NEUTRONS, PROTONS, AND HEAVIER)

H. H. Rossi, chairman
E. P. Blizard
R. S. Caswell
F. P. Cowan
D. B. Cowie
T. C. Evans
D. J. Hughes
L. D. Marinelli
W. S. Snyder
C. A. Tobias

SUBCOMMITTEE 5. ELECTRONS, GAMMA RAYS AND X-RAYS ABOVE 2 MILLION VOLTS

H. W. Koch, chairman
G. C. Baldwin
C. B. Braestrup
D. B. Cowie
U. Fano
J. S. Laughlin
L. D. Marinelli
D. Scag
L. S. Skaggs

SUBCOMMITTEE 6. HANDLING OF RADIOACTIVE ISOTOPES AND FISSION PRODUCTS

H. M. Parker, chairman
P. C. Aebersold
G. Failla
S. Feitelberg
J. G. Hamilton
D. Hull
L. D. Marinelli
J. E. Rose
W. K. Sinclair
M. M. D. Williams

SUBCOMMITTEE 7. MONITORING METHODS AND INSTRUMENTS

H. L. Andrews, chairman
C. B. Braestrup
J. Healey
R. Lapp
R. G. Millar
W. H. Ray
J. E. Rose
E. G. Williams

SUBCOMMITTEE 8. WASTE DISPOSAL AND DECONTAMINATION

J. H. Jensen, chairman

NOTE.—This subcommittee has been inactivated and will probably be reorganized.

SUBCOMMITTEE 9. PROTECTION AGAINST RADIATION FROM RA, CO-60, AND CS-137 ENCAPSULATED SOURCES

C. B. Braestrup, chairman
H. Blatz
M. Brucer
T. P. Eberhard
G. Ferlazzo
E. H. Quimby
E. L. Saenger
H. O. Wyckoff

SUBCOMMITTEE 10. REGULATION OF RADIATION EXPOSURE DOSE

L. S. Taylor, chairman
W. E. Chamberlain
P. C. Hodges
R. R. Newell
E. P. Pendergrass
J. G. Terrill, Jr.
E. D. Trout
F. Western
E. G. Williams

SUBCOMMITTEE 11. INCINERATION OF RADIOACTIVE WASTE

G. W. Morgan, chairman
R. C. Corey
S. Feitelberg
W. H. Langham
J. A. Lieberman
L. Silverman

SUBCOMMITTEE 12. ELECTRON PROTECTION

L. S. Skaggs, chairman
E. A. Burrill
H. W. Koch
J. S. Laughlin
R. F. Post
E. D. Trout

SUBCOMMITTEE 13. SAFE HANDLING OF CADAVERS CONTAINING RADIOACTIVE ISOTOPES

E. H. Quimby, chairman
S. Feitelberg
L. R. Peet
W. B. Stewart
R. Yalow

SUBCOMMITTEE 14. PERMISSIBLE EXPOSURE DOSES UNDER EMERGENCY CONDITIONS

L. S. Taylor, acting chairman
H. L. Andrews
H. Blair
G. Cassaret
G. Dunning
E. Green
R. Hesterlik
G. V. Leroy
E. G. Williams

SUBCOMMITTEE M-1. STANDARDS AND MEASUREMENTS OF RADIOACTIVITY FOR RADIOLOGICAL USE

W. B. Mann, chairman
T. P. Eberhard
K. W. Geiger
W. Gross
R. Rugh
W. K. Sinclair

SUBCOMMITTEE M-2. STANDARDS AND MEASUREMENT OF RADIOLOGICAL EXPOSURE DOSE

H. O. Wyckoff, chairman
C. B. Braestrup
R. S. Caswell
C. Garrett
J. Hale
J. S. Laughlin
R. R. Newell

SUBCOMMITTEE M-3. STANDARDS AND MEASUREMENT OF ABSORBED RADIATION DOSE

G. Failla
G. S. Hurst
H. W. Koch
H. M. Parker
W. C. Roesch
H. H. Rossi
G. N. Whyte

NOTE.—Arrangements for the chairmanship of this subcommittee have not been completed.

SUBCOMMITTEE M-4. RELATIVE BIOLOGICAL EFFECTIVENESS

W. Langham, chairman
V. Bond
R. Evans
T. Evans
J. Storer
A. Upton
C. Tobias
J. Stannard
Miriam P. Finkel

NOTE.—This subcommittee is being activated and the membership organization has not been completed.

NCRP EXECUTIVE COMMITTEE MEMBERSHIP

L. S. Taylor (chairman), National Bureau of Standards, Washington, D. C.
E. C. Barnes, Westinghouse Electric Corp., Post Office Box 1468, Pittsburgh, Pa.
C. B. Braestrup, physics laboratory, Francis Delafield Hospital, 99 Fort Washington Avenue, New York, N. Y.
C. L. Dunham, Division of Biology and Medicine, United States Atomic Energy Commission, Washington, D. C.
J. Bentley Glass, department of biology, Johns Hopkins University, Baltimore, Md.
H. M. Parker, General Electric Co., Hanford Works, Richland, Wash.
Clinton Powell, Division of Special Health Services, United States Public Health Service, Washington, D. C.

R. S. Stone, medical center, University of California, San Francisco, Calif.
Shields Warren, Cancer Research Institute, New England Deaconess Hospital, 194 Pilgrim Road, Boston, Mass.

CONSULTANTS

J. C. Bugher, medical education and public health, Rockefeller Foundation, 49 West 49th Street, New York, N. Y.
G. Failla, department of radiology, Columbia University, 630 West 168th Street, New York, N. Y.
E. G. Williams, Division of Hospital and Medical Facilities, Public Health Service, Room 1525, Temporary R, Washington, D. C.

(Mr. Taylor's statement—continued.)

TRENDS OF PROTECTION STANDARDS

The trends of protection standards has been steadily downward. This is partly because of improvement in our knowledge and partly because a constant improvement in the techniques in the use of radiation make it possible to revise the standards downward. The two factors are in constant interplay. The most recently recommended permissible dose levels must be regarded now as practically at rockbottom if we are to continue to use radiation at all. Exposures for persons in the environment of plants are only 3 or 4 times the level of natural background radiation. Since in some circumstances, background radiation may be several times higher than the average it makes little sense to attempt to work to much lower levels.

EXHIBIT 18. MAJOR STEPS IN THE DEVELOPMENT OF PROTECTION STANDARDS

(Item V F-4 in outline)

1925: ICRU established by First International Congress of Radiology:
MPD=0.1 erythema dose/r=50–100 r/yr (only visible signs of radiation reaction)
1926: ICRP established by Second International Congress of Radiology:
(a) First set of international protection recommendations adopted.
(b) First unit of dose adopted: the roentgen (r)
1929: NCRP formed in the United States.
1931: First set of radiation protection rules produced by NCRP (H-15).
1934: ICRP:
(a) Adopted first permissible dose of 0.2 r/day (=72 r/yr).
(b) Based on erythema dose.
1935: NCRP:
(a) Adopted value of 0.1 r/day for MPD (=36 r/yr).
(b) More conservative MPD adopted on basis of their suspected other effects.
(c) First discussions on genetic effects.
1947: NCRP:
(a) Lowered MPD to 0.3 r/wk (=15 r/yr).
(b) Lowered because of animal experience in Manhattan District studies.
(c) Genetic effects considered. (See H-59.)
(d) Longevity effects considered.
(e) Large population effects considered.
(f) Standards still based mainly on absence of detectable injury to individuals.
1950: ICRP:
(a) Adopted MPD=0.3 r/wk.
(b) Used values of NCRP for standards for external irradiation.
(c) Used unpublished values of NCRP for internal emitters. (See H-47.)
1952: ICRP/ICRU:
(a) Held first conference on genetic effect.
(b) Reached conclusions essentially as recommended by ICRP in April 1956 and NAS in June 1956.
(c) Felt there was no need to rush to lower levels—better to wait for better data.
(d) Still feel somewhat same about lowered MPD but were stampeded by public clamor.
1953: NCRP listed MPC for 100 radioisotopes (H-52).

1953: ICRP:
(*a*) Adopted NCRP listings of MPC for 100 radioisotopes.
(*b*) Recommended 1/10 levels for large population groups.
1953: ICRU adopted unit of absorbed dose (rad).
April 1956: ICRP introduced accumulated dose concept for both occupational and whole population exposure.
June 1956: NAS/BMRC made same general recommendations as ICRP. (Natural in view of substantial overlap of membership.)
January 1957: NCRP:
(*a*) Formulated the age-prorated occupational dose to insure proper distribution with age.
(*b*) Population dose concept of ICRP adopted.
April 1957: ICRP/ICRU:
(*a*) In work for UNSC made recommendations population exposure evaluations by sampling techniques.
(*b*) Tentatively decided that somatic damage is more immediately important than genetic damage.

(Mr. Taylor's statement—continued.)

The impact of the new standards on our budding nuclear industry will not be as serious as might be thought at first glance. The major atomic energy installations have been working within the new levels for years.

EXHIBIT 19—THE IMPACT OF LOWERED RADIATION EXPOSURE LEVELS ON RADIATION CONTROL PROBLEMS

Lauriston S. Taylor, Atomic and Radiation Physics Division, National Bureau of Standards

You have already heard, in the preceding paper, about the proposed lowering of the levels of maximum permissible dose for radiation workers, and the general population, as proposed by the International Commission on Radiological Protection at its meeting in April of last year. In essence these new recommendations call for a reduction in the MPD by a factor of about 3, as compared with the levels that have been allowed for the past 10 years. The phraseology of these recommendations, in keeping with the normal pattern of the ICRP, was left in somewhat general terms, thus allowing to each country the opportunity of incorporating them in the normal pattern of their individual protection codes or recommendations.

The impact of these proposed changes will be quite different depending upon whether the source of radiation is external to the body or is from radioactive emitters that may enter the body. The impact will be substantially different as between the present type of large-scale atomic energy operations, scattered industrial operations, or the medical uses of X-rays and radioactive isotopes. Probably the most severe difficulties will arise in connection with the further reduction of the permissible exposures to external radiation that will be allowed to persons outside of controlled areas.

With regard to population exposure, the ICRP made the statement that, "It is prudent to limit the dose of radiation received by the gains from all sources additional to the natural background to an amount of the order of natural background in presently inhabited regions of the earth."

At the November meeting of the ICRP, there was considerable debate centered about this point, and it was then agreed that "by the order of natural background" was meant, not equal to natural background but approximately twice the background. Thus in clarification of the earlier statement, the ICRP allowance for general population exposure, will be an average of 10 rem to the gonads up to age 30, and 10 rem per decade thereafter.

The statement was also made that the average exposure of radiation workers should be about 5 rem per year. Considerable fear was expressed that by stating this latter figure in such simple terms, undue hardship on all radiation applications might result, if it were to be interpreted so literally that no individual was allowed to receive an excess of this amount in any 1 year. Various attempts were made to introduce some latitude in this interpretation but at the moment I am not sure as to what the final decision was.

The difficulty up to now is dealing with a single number giving the individual's total permissible lifetime exposure, is introduced because of the fact that the safety recommendations of a few years ago have now entered our

legal machinery and are now legal requirements backed up by varying degrees of enforcement. For the 25 years beginning with the appearance of the first NCRP Handbook in 1931, radiation safety control in this country was on the basis of recommendations backed up by voluntary compliance and good sense. It must be admitted that there were times when neither compliance nor good sense prevailed, but in the great majority of situations it did.

The basic scientific aims and information regarding permissible radiation exposures have been well understood for a number of years. On the other hand, there have been situations where the information was capable of misinterpretation by people who were inexperienced in the field. Partly as a result of this, there has been increased tendency on the part of industry and by State and Federal Government to call for strict codification and the development of radiation protection rules wherein a situation is either black or white. Here begins our trouble.

Let us consider as acceptable a total accumulated exposure of 250 rem over a period of 50 years, up to age 70. Now it is obviously impossible, with any means that we now know of, to measure and record this exposure for each individual. For the purposes of design and operation, one might want to integrate the exposure over a shorter period of time, say 1 year, in which case the average allowable amount would be 5 rem. This is also difficult to control but it is suspected that before too long adequate instrumentation will be obtainable such that this can be done within adequate accuracy limits. At least as far as plant operations are concerned the level of 5 rem per year is a much better figure to work with.

It is important to limit the exposure to individuals during their childbearing age. For this purpose the NCRP is recommending a permissible exposure of approximately 60 rem up to age 30, and an additional 50 rem up to age 40.

Here again it is important to assure adequate distribution of this dose over time. If one considers that 50 percent of the children are born to parents by the time they reach age 30, and 90 percent by the time they reach age 40, it is clearly more important to curtail exposure at the lower end of this age range than at the upper age range. There would be a large difference in the total genetic damage due to an exposure of 50 rem at age 20, as compared to the same exposure at age 30. At the age of 40 this exposure would only affect 10 percent of the genes that might be expected to be transmitted. Consequently there is some wisdom in stating that for operational purposes the average occupational exposure of individuals should not exceed 5 rem per year.

But even here there are difficulties. Suppose that the NCRP were to recommend 5 rem per year for the basic permissible level as compared with the present level of 0.3 rem per week. As soon as this figure is even mentioned it will find its way into various laws and regulations. Everything automatically becomes black or white and any individual who may be so unfortunate as to receive 5.001 rem in any 1 year might think he had legal grounds for seeking redress from his employer. This is, of course, sheer nonsense and yet it is difficult to develop a law in this field in which there is adequate latitude for such reasonableness. The NCRP has worried a great deal about this problem and various suggestions have been put forward.

Consider the cost to a plant operation of a legal limitation of 5 rem per year to the individual worker. Plant management would be foolish to plan their operations in such a way that part or all of its workers would be allowed to take a dose closely approaching 5 rem per year. Experience has demonstrated that surely 1 or 2 people are going to accidentally exceed this and even though we know that a slightly higher exposure is without harm the employee might seek redress. Because of this fear, the plant must plan its operation so that in general they will not exceed, say, 40 or 50 percent of the permissible exposure. This can be very costly and time-consuming and could seriously retard the atomic energy industry.

It has also been suggested that the yearly limit be specified as 5 rem plus or minus 20 percent. This would certainly simplify plant planning and operations but I am very doubtful as to how and whether this could be dealt with to the satisfaction of our legal authorities. Another suggestion has been to specify a total exposure not exceeding 50 rem in 10 years delivered at an average rate not exceeding 5 rem per year. Here again this situation is wide open to abuse or difficulty in legal interpretation. For example, an employer could allow an individual to receive 25 r in each of 2 years and then

lay him off under circumstance which would make him unemployable in the radiation industry. Also this would be unacceptable because one should not allow an individual at the beginning of his reproductive age to receive this large dose. If he is to have a large dose it is much better that he receive this after the conception of his last child and this, of course, changes with age.

Another alternative is to specify the 5 rem per year average but with the further stipulation that no one be allowed to receive in excess of 10 rem in any consecutive 2 years. Even this would allow some abuse but such a provision would vastly simplify plant operations. For example, if an occupational individual received, say, 6 rem in 1 year it would be up to the plant to insure that he could receive no more than 4 rem in the following year. If one decides on an average figure of 5 rem per year the plant will design accordingly. The plant will possibly go further than this since control over a year is not always easy. It may well, for purposes of simplicity, make its designs so as not to allow the exposures to exceed 0.1 rem per week, which is one-third of the present maximum permissible exposure.

The National Committee on Radiation Protection has been increasingly concerned, over the past year, by the trend to incorporate its recommendations into documents having legal status. Almost invariably when this is done, the degree of suppression of radiation exposure goes beyond the philosophies of the committee. As a rule these are in the direction that tend to hamper the applications of radiation, without at the same time, providing any real and significant improvement in radiation protection. In an endeavor to curtail unduly restrictive interpretations of the relatively simple basic rules for radiation protection, there has been a tendency in the past for the National Committee to include in its recommendations various modifications and interpretations of its basic rules. Because of this, the administrative problems involved in radiation control have become more complicated.

I mention this situation because unless great care is taken in the future with our lowered permissible exposure levels, their administrative control may become so restrictive as to make certain types of radiation usage impractical.

It is for this reason that in its latest recommendations the National Committee has tied its basic permissible exposure to the individual's age, rather than to a limitation determined on the basis of a week or even a year of radiation exposure. The basic protection requirement now specified by the National Committee is designed to assure that a person will not receive an average of more than 5 rem per year occupational exposure during his working lifetime from age 18 to 70. In order, however, to get away from the legal statement of 5 rem per year, it is now recommended that individuals be allowed to receive a dose in rems equal to five times the number of years over age 18 of that individual's age. This will tend to hold down exposure at the younger ages when it is genetically more important. It will allow the building up of a reserve of exposure in situations where an individual's age-prorated exposure is less than that allowed.

Any wise management must employ operating safety factors in his allowable radiation exposures and if these are tied rigidly to periods as short as a month or a year, the cost to the plant of introducing the radiation safety factors can be very great. With the new system there is ample latitude for taking care of the very rare instance where an individual may for some reason or other have exceeded an average weekly, monthly, or yearly radiation exposure.

The new recommendations, even though three times lower than the earlier ones, will place a premium on good management. For example, in a large operation it will certainly pay to have good monitoring and recording procedures. Where it can be demonstrated beyond reasonable doubt that an individual's exposure through the use of these is below the permissible amounts, management can permit its employees to build up a reserve exposure. The larger the reserve the greater the flexibility in the use of that employee in subsequent operations. For small operations the cost of instrumentation and recording may be unduly costly, in which case it would probably be more economical to simply set the operating exposure levels low enough so that relatively infrequent monitoring will suffice to assure adequate protection of the individual.

The new recommendations, as well as the old, have specified that the levels of radiation exposure for individuals outside of controlled areas can only be one-tenth of those permitted within controlled areas. This means that on the average a person outside of the controlled areas can receive only 0.5 rem per

year. This is a level which under most circumstances is only a few times greater than background and will in some cases necessitate substantial increases in existing shielding, or means for further reducing the admission of certain contaminants into the air or water. In the case of radiation from external sources, radiation levels outside of controlled areas will have to be reduced to about one-thirtieth of the present MPD allowed workers within a plant at the present time. This may make for difficulties in situations where persons in uncontrolled areas are in very close proximity to sources within a controlled area. On the other hand, the range of such hazard is relatively limited since the dose rate falls in accordance with the inverse square law. From the point of economics it is, therefore, desirable to separate as far as possible controlled and occupied uncontrolled areas. This situation is not likely to seriously affect atomic energy operations even at the new low levels. It will create new problems in the use of byproduct materials.

For radioactive contaminants in the air, the problem is simpler on one hand and is more complicated on the other. The new permissible levels for internal emitters will not be substantially different from the present permissible concentrations except in a very few cases. These cases will include the situations where the critical organ is the gonads or the whole-body and as far as our knowledge goes today, these are the critical organs only for tritium, sodium, and phosphorous. In other words, the new levels for permissible concentrations of radio-nuclides in air and water will not materially affect present-day practices.

Airborne activity carries with it the usual difficulty in no way changed by the lowered levels. This difficulty is introduced because of the fact that such contaminants may stray very great distances from the original sources so that one needs to be concerned about population protection outside of controlled areas covering a much greater area than would be involved in the case of the radiation from external sources.

Let us examine rather briefly some of the areas that may or may not be affected by the lowered permissible levels.

The present impact on nuclear industry will be relatively small insofar as their own operations are concerned. Within the plants of the Atomic Energy Commission and its contractors, there is already a history of amazingly low radiation exposure levels to individuals. The vast majority of the individuals in controlled areas receive today less than 1 rem per year. Only a very small number receive up to the full allowance of about 15 rem per year and I believe that only 2 or 3 out of some 65,000 persons during the past year exceeded the yearly allowance. In other words, these operations are already working well within the new limits.

As already noted, contamination levels of air and water are not going to be substantially changed except for 2 or 3 radio-nuclides. Consequently if the industry has been providing adequate protection in the past it can continue to do so in the future without serious additional strain.

The impact of the lowered levels on other applications of radiation may be more severe particularly with regard to the use of X-rays, sealed sources of radioactive material and accelerators. In the nonnuclear industry where isolated sources of radiation may be scattered around a plant or in various parts of a city there has frequently been the tendency to allow exposure levels of both occupational and nonoccupational persons to go up fairly close to the ceiling. In those instances where this has been the practice additional shielding is going to be required. This can be costly when it comes to making additions and alterations to existing installations. The matter will not be too serious in new installations. In general it simply means adding approximately two half-value layers of shielding material over what has been required up to the present.

The impact on the medical uses of radiation will also be relatively severe. Here because of the nature of the work, it is necessary for the physicians and to a lesser extent the technicians, to expose themselves to some degree of radiation. To accomplish their medical task it is often necessary to take unto themselves some degree of risk beyond that expected in other types of operations. To achieve the newly imposed levels will necessitate some changes in working procedures and some improvements in equipment design and shielding. Also some improvement will, in all probability, be needed in the shielding normally surrounding the rooms where radiation is used. Greater care will also have to be taken to assure that radiation that escapes from the controlled area does not penetrate to uncontrolled areas that may be occupied by persons not subject to radiation monitoring. The radiological profession is always

fully conscious of this problem and over the years have established a very creditable record of constant improvement in their protection practices.

In closing, a few remarks should be made about the effects of medical exposures to radiation superposed on occupational exposures. This is a question that arises frequently and for which there is no simple solution. For practical reasons the various national and international bodies concerned with radiation protection problems have been forced to exclude from consideration the added effects of radiation received by an individual for medical reasons. At the moment this is not too serious. At present the occupational exposure per million people amounts to only about 3 percent of that received for medical reasons. From a genetic point of view this amount is insignificant and one can neglect occupational exposure in relation to medical exposure, when dealing with an average over a large population group. The situation may be more serious for the occasional individual who may receive both the maximum occupational exposure and a large medical exposure. While it is not feasible to regulate or control these in relation to each other, it would be prudent for the employer to keep aware of such situations and make allowance for them in the assignment of an individual to further radiation work. It would also be prudent on the part of the employee to inform his physician that he is a radiation worker and that any additional medical radiation should be kept to a minimum. The decision on this is then up to the physician. It will only be in the rare instance when the two types of exposure can be compounded to dangerous proportions. In such instances it will usually be the case that the individual's well-being or even life is at stake for reasons unassociated with any radiation damage to himself.

(Mr. Taylor's statement—continued.)

The basic assumptions on which permissible exposure is based have changed emphasis several times. Originally, the permissible dose level was based on the erythema or visible skin-burn. Later, emphasis was shifted to any detectable injury that might occur to the individual. More recently, there has been great emphasis placed on the genetic damage to reproductive cells. It is now beginning to appear that the somatic effects on the individual may be the more critical item. In spite of these changes of emphasis the trend has been toward becoming more critical rather than less critical.

THRESHOLD LIMITS

There is presently a great deal of uncertainty as to whether or not there exists any threshold limit for radiation exposure below which damage will not occur. A probable exception to this is genetic damage. In arriving at permissible dose levels it has never been assumed that there were any thresholds for radiation injury. Damage to an individual from any exposure is a matter of probability and the limits are believed to have been set low enough to make the risk small and acceptable. There is always some risk involved in radiation exposure but also there is risk in virtually everything else that we do. With radiation the problem is to balance the risk by exposure against the tangible and intangible gains to be gained by this exposure and against the risks that occur from a variety of other sources.

Exhibit 20. Permissible Exposure to Ionization Radiation, International Conference on Peaceful Uses of Atomic Energy, June 1955, Geneva, Switzerland

By Lauriston S. Taylor, National Bureau of Standards

This short note, reflecting the general opinions of most members of the National Committee on Radiation Protection, directs attention to a major problem that must be faced when we consider large-scale peaceful developments of nuclear energy. The problem directly influences our whole philosophy with regard to radiation protection and centers about the fact that the genetic effects of low-level exposures of a large fraction of the population may ultimately decide the permissible dose for all persons. Up until relatively recently the prime consideration in deciding upon the maximum permissible dose of ionizing radiation has been the exposure of the single individual. Future considerations of the maximum permissible dose may conceivably involve an entirely new feature; whereas past decisions have been based on scientific principles alone, future decisions may have to include political and economic factors.

The current maximum level of permissible exposure for the single individual rests on the philosophy that exposure at this level throughout his adult lifetime is believed unlikely to cause him bodily injury at any time during his lifetime. Based on this major premise, the present permissible exposure levels are acceptable both from the plant and the individual's viewpoint, and do not appear to involve an unreasonable working risk. Such levels are, however, also based on the additional premise that only a small portion of the world population will be so exposed up to the close of their reproductive lifetime.

On the other hand, where large population groups may be exposed, the preservation of the genetic balance of the population may require that the exposure per individual be limited to only a very small fraction of the individual occupational exposure.[1] Up to the present, most of the pertinent data is from animal rather than human experiments, yet we are forced to accept tentatively the animal data as applying to man.

For purposes of discussion, let us take Muller's[2] statement that an exposure of 80 r to the gonads would double the natural mutation rate and that such exposure repeated generation after generation might seriously upset the genetic equilibrium. Presumably this would be genetically unacceptable in view of the doubly heavy genetic load thrust upon the unexposed population, and in view of the present trends in reproductive practices. Muller suggests a maximum average exposure per individual per reproductive lifetime of 20 r, which would result in an increase in the mutation rate of only 25 percent. Other authorities have arrived at figures as low as 3 r for a permissible average "lifetime" exposure. Either figure is much lower than the presently accepted individual occupational exposure limit which may be as high as about 400 r per lifetime.

If we are to adhere to the 20 r average for the whole population, not more than 5 percent of the people could be permitted to receive a full occupational exposure of 400 r to the gonads. For the United States this would be some eight million persons—a figure that we are unlikely to attain for many years to come. One should also consider that most radiation workers do not receive exposures over periods as long as 25 years, and that in fact only a very small number receive more than about one-third of the permissible exposure. On the other hand, there must be added to this, medical and diagnostic exposures wherein radiation may reach the gonads.

Before facing the problem of determining how much additional radiation may be received by nonoccupational population groups, it is essential to make a careful evaluation of existing exposure patterns. Since the prime consideration will be genetic effects, such exposure evaluation should be limited to the gonads of persons before the close of their reproductive lifetime.

Concurrent with, or a part of, such a study should be certain sociological investigations. Reproduction habits will play an important role, and these will vary markedly depending upon such factors as race, education, inbreeding within certain geographical limits, etc. In averaging the exposure of population groups, erroneous results would be obtained by equal weighting of say the population of New York City and an Indian reservation in the West.

Since the size, distribution, and nature of a population group may influence the pattern of crossbreeding, it may be worthwhile even within a single country such as the United States, to consider very different average exposures for different parts of the country. Such differentiation might present almost impossible administrative problems because of population movements, yet there are relatively large and different population groups between which crossbreeding is negligible. This same consideration will, however, be likely to necessitate lowering of average exposures in some areas where inbreeding is high within a population group that remains somewhat static in location. (This may be somewhat less of a problem in cities of the United States as compared with those of Europe and Asia.) There will undoubtedly be special problems of this sort in certain areas and it might be worthwhile to treat them specially, rather than inflict unnecessarily low permissible exposures over the country as a whole. Analysis of individual situations, while costly to perform, may nevertheless be sound economy in the end.

From the point of view of power reactors, the limits set for radioactive wastes will vary considerably, dependent upon location. This, of course, has been one of the prime considerations in locating reactors thus far, and each case has been treated on its own merits.

We have to face the high probability of an enormous growth in the uses of nuclear energy. It is doubted whether anyone has ventured to predict this for the next 20 or 100 years. Looking backward at the enormous changes in our civilization brought about by technilogical advances in the past 4 or 5 generations, indicates the futility of planning ahead in detail a similar range of time. This does not imply, however, that we should stand passively by and let nature take its course. There is much that can be done in preparation for the future.

As the invention of the internal combustion engine revolutionized the world, so also may we expect controlled nuclear energy to do so again. The engine has wrought vast improvements into our material ways of life. One wonders whether, if in 1910 it had been anticipated that the engine would be responsible 40 years later for 30,000 deaths a year on United States highways alone, there would have been a hue and cry to curtail its further use. In spite of the fact that we somehow accept this carnage, we might have been able to have held it down, had the problem been attacked while automobiles were in their infancy.

With nuclear energy the situation is importantly different—even if more complicated. We know a great deal about its potential hazards and to some extent how to cope with them. In addition, we have some time within which to solve the special problems. However rapid the growth in the use of atomic energy, there is still some leeway that will allow us to proceed with technological developments before we outrun our practical limits in the methods of protection. The greatest and most serious limitation is that imposed upon us by genetic considerations. Our most substantial advances in knowledge of genteics have been within the past two or three decades—a very short time. The results of this knowledge have been a major consideration in the discussion leading to our present concepts of permissible dose, yet we have avoided any attempts to rigorously define the genetic limitations. (It is presumed that the geneticists, to be safe, assume the most pessimistic conditions.

At some time, probably not within the immediate future, man will be faced with making an inescapable decision. At what point may the advantages of atomic energy be offset by the disadvantages to the future man? And who will have the abundant wisdom to recognize that point and do something about it? Will it be known, in time for such a decision, just what radiation may do to man's future? I believe that at some point a decision involving an educated gamble with man's future will have to be made, and history of the past indicates that such a decision may be made on the less rather than the more conservative side. The decision does not need to be made tomorrow or probably for some years. In the meantime, we can continue our present pace with relatively little risk. But in that same meantime, it is felt that we should start to condition our thinking for a change in philosophy with regard to radiation exposure. On the basis of today's knowledge of ourselves, we may be expected to show a willingness to accept more rather than less radiation exposure insofar as its effects 10 or 20 generations hence may be felt.

In this same time, we should also devote our every energy to keeping radiation exposure of persons to the minimum compatible with reasonable progress and good sense. Through education and the dissemination of wisely chosen information, we can do much better than at present in matters of radiation protection, without at the same time fettering a source of great benefit to mankind. The better we do the ordinary job of protection today, the longer we postpone the fateful decision on man's future.

There has been a tendency to believe that maximum permissible dose levels can be established on a firm and irrefutable physical basis. This is certainly not true. The establishment of proper dose levels is importantly a matter for physics and biology. It is, however, equally important in reaching a final conclusion that we exercise the highest standards of morality and ethics, and that we bring to bear our utmost in wisdom.

For many years the risk due to radiation has obviously been very small. Even though the standards of the past have been much more liberal than those of the present, we are today forced to the conclusion that the effects of radiation are so slight for such small exposure that it is difficult to establish a causative relation-

ship between exposure and damage even with the more critical of statistical sampling.

RECORDING OF DOSE FOR THE POPULATION

For many years the NCRP and ICRP have considered the problem of recording the dose of all individuals as an aid in the statistical studies of the effect of small or moderate radiation exposures on man. Such a plan has always been ruled out because even at enormous cost their results would have so many uncertainties introduced by poor input data from medical usage as to render useless the application of the information for statistical analysis.

The International Commission on Radiological Protection and the International Commission on Radiological Units and Measurements have completed a study of this question as a result of a specific request from the U. N. Scientific Committee on the Effects of Atomic Radiation. This study substantiates the conclusions mentioned above, namely that at the present time and for the immediate future any system for recording individual medical dose given during diagnostic medical procedures is without value. This applies to recording either by a card-carrying system or by a central recording agency. On the other hand, the commissions do recommend the establishment of sampling procedures, which will provide useful information if carried out on a systematic basis. The cost of such surveys will be only a small fraction of that for a universal registration system and yet will give results with an accuracy commensurate with that of the input data. At the same time it is expected that the input data can be improved by the sampling technique as it goes along.

(Exhibit 21 to be filed with the committee at a later date.) (Material consists of the preliminary report of the ICRP/ICRU to the U. N. and is submitted for use by the Committee. Since the report is not in final form it is requested that it not be published in the record. If the Committee wishes to include a final report of the international commissions one can be made available by about the middle of July.)

EXHIBIT 22. REPORTS OF UNITED STATES TASK GROUP

UNITED NATIONS,
New York, November 5, 1956.

File: PO 131/242.
Prof. ROLF SIEVERT,
Chairman, International Commission on Radiological Protection,
New York, N. Y.

DEAR PROFESSOR SIEVERT: It is my pleasant duty to transmit to you, in your capacity as chairman of the International Commission on Radiological Protection, the following resolution passed unanimously by the Scientific Committee on the Effects of Atomic Radiation at its second session:

The Radiation Committee

Recognizing that in certain countries[1] one of the most important contributions to the present irradiation of human populations caused by manmade sources of ionizing radiations has been shown to originate from the use of radiation in the diagnosis and treatment of diseases;

Believing that a careful study of the doses, particularly to the gonads, received by patients undergoing radiological treatment and examination is desirable;

Believing that the International Commission on Radiological Protection and International Commission on Radiological Units and Measurements by virtue of their connection with the radiological profession are the most suitable bodies to study the problem of recording, measurement and evaluation of doses involved and having reason to believe that they would be interested in doing so;

Invites the International Commission on Radiological Protection together with the International Commission on Radiological Units and Measurements—

(*a*) to consider and discuss the question of how to arrive at reliable data indicating the doses to different parts of the body (particularly the

---

[1] See reports submitted to the Committee by Sweden, the United Kingdom, and the United States.

gonads) received by individuals and, in the aggregate, by large population groups due to the medical use of ionizing radiations;

(*b*) to examine what recording system, if any, is at present feasible for the determination of the relevant dose values; and

(*c*) as a result of these studies, to submit to the Scientific Committee on the Effects of Atomic Radiation as soon as possible, and in any event before September 1, 1957, a report upon their deliberations and conclusions on the subjects (*a*) and (*b*), and to make any appropriate recommendations;

Requests the Secretary General to make the necessary arrangements with the two Commissions to implement the above invitation, including provision for reimbursement of expenses incurred by them to an amount not exceeding $10,000.

May I ask you to place the resolution before your members, and to inform me whether the Commission accepts the invitation contained in it. Upon receiving from you an affirmative response, which I appreciate may be conditional upon the financial support mentioned, I will seek the necessary authority for expenditure under the last clause of the resolution.

May I, in conclusion, express my personal hope that this marks the initiation of a prolonged, close and fruitful cooperation between all of the international bodies concerned.

Yours sincerely,

(Signature) RAYMOND K. APPLEYARD,
Acting Secretary, Scientific Committee on the Effects of Atomic Radiation.

NOTES.—1. A similar letter has been received by the Chairman of the ICRU. 2. It was decided at the New York joint meetings that the $10,000 would be used to assist in paying the travel expenses of the task group.

OUTLINE OF STUDY FOR U. N. SCIENTIFIC COMMITTEE ON EFFECTS OF ATOMIC RADIATION

I. INTRODUCTION

The ICRP and ICRU have recently been invited by the U. N. Scientific Committee on the Effects of Atomic Radiation to study the radiation dose received by various organs of the body when persons are undergoing radiation examination and treatment (see ICRP/56/41 or ICRU/56/23). It should be noted that the Committee has asked for evaluation and recommendations of *methods* for determining the dose and not for detailed data. However, it may be necessary to obtain some exploratory data in order to set limits for accuracy. It should also be noted that the present request could be interpreted as being limited to examination and treatment, but it is considered desirable to include occupational exposures. While it is thought that at the present time the latter adds only small amounts to the radiation burden of the world population, this should be examined at some future date.

At a recent informal meeting of the two Commissions, methods of facilitating the study were discussed. Several methods were suggested and are incorporated in ICRP/56/44, ICRU/56/27, but others may be thought of in the process of obtaining information by those methods suggested. If these are suggested in time, they can also be included in the study.

II. ORGANIZATION

As this problem is principally one of protection, the work will be coordinated by the Secretary of the ICRP, Mr. Walter Binks. He, together with the other officers of the ICRP, the officers of the ICRU, and members of the Commission assigned to coordinate the various tasks constitute the Task Group.

The study has been divided into the following tasks (discussed in more detail in ICRP/56/44, ICRU/56/27):

Task 1. General: Gonad dose versus skin dose and average dose per examination.

Task 2. Complete recording for entire population.

Task 3. Sampling procedure.

Task 4. Approximate methods:
(a) Health and social security agency records
(b) Film or X-ray tube records
(c) Questionnaire to professional people.

Task 5. Dose from unsealed radionuclides.

Given below are the names and addresses of the task group and the Commission task assigned to each:

Chairman, ICRP: R. Sievert, Institute of Radiophysics, Stockholm, Sweden
Vice Chairman, ICRP: G. Failla, department of radiology, Columbia University, 630 West 168th St., New York, N. Y.
Secretary, ICRP: W. Binks, National Radiological Protection Service, Clifton Ave., Belmont, Sutton, Surrey, England
Chairman, ICRU: L. S. Taylor, National Bureau of Standards, Washington, D. C.
Vice Chairman, ICRU: L. H. Gray, radiobiological research department, Mount Vernon Hospital, Northwood, Middlesex, England
Secretary, ICRU: H. O. Wyckoff, National Bureau of Standards, Washington, D. C.
Task 1: E. E. Smith, National Radiological Protection Service, Clifton Avenue, Belmont, Sutton, Surrey, England
Task 2: E. A. Watkinson, environmental health and special projects, National Health and Welfare, Jackson Building, Ottawa, Ontario, Canada
Task 3: K. Z. Morgan, Health Physics Division, Oak Ridge National Laboratory, P. O. Box P, Oak Ridge, Tenn.
Task 4: A. Allisy, Laboratoire de Recherches, Ecole Normale Superieure, 24 rue L'homond, Paris, France.
Task 5: W. G. Marley, Health Physics Division, Atomic Energy Research Establishment, Harwell, Didcot, Berkshire, England.

A national leader has been named to provide a focal point in each of the countries conducting this study. He is responsible for naming national task leaders to consider each one of the tasks. During the meetings of the two Commissions, nationals of seven countries were present. Accordingly, it was possible to appoint the following national leaders at that time:

Canada: E. A. Watkinson, environmental health and specialist projects, National Health and Welfare, Jackson Building, Ottawa, Ontario, Canada.
France: L. Bugnard, Institut National d'Hygiene, Ministry of Health, 3 rue Leon Bonnat, Paris 16E, France.
Germany: H. Holthusen, Direcktor de Strahleninstitut Krankenhauses St. Georg, Hamburg, Germany.
Sweden: R. Sievert, Institute of Radiophysics, Stockholm, Sweden.
United Kingdom: E. E. Pochin, Department of clinical research, University College Hospital Medical School, University Street, London W. C., England.
United States: L. S. Taylor, National Bureau oif Standards, Washington, D. C.
Urugay: F. E. Leborgne, Institute of Radiology, Hospital Pereira Rossell, 1210 Ibicuy, Montevideo, Uruguay.

Other countries having nationals on either of the commissions or their committees are invited to cooperate, as are the radiological societies of all the other countries officially represented at the 8th International Congress of Radiology at Mexico City.

No information is yet available on the names and addresses of national task leaders.

III. OUTLINE OF PLAN FOR STUDY

1. National Studies

(a) Names and addresses of national task leaders to be sent by national leader to all members of the task group by December 15, 1956.

(b) Copies of correspondence between commission task leaders and national task leaders should be sent to national leader.

(c) Reports (in English) to be sent by national leader to each member of task group by March 1, 1957. (Individual reports on tasks should be sent to commission task leaders as completed to allow more time for their study.)

2. Commission study

(a) Commission task leaders to prepare and distribute consolidated report on their tasks to all participants in the study (task group, national leaders, and national task leders) and to ICRP and ICRU main commissions by April 1, 1957.

(b) Fifteen copies of each person's comments on consolidated reports to be sent to ICRP Secretary in Geneva before April 19, 1957.

(c) Meeting in Geneva of task group April 23–27, 1957, to prepare draft of final report.

(d) Draft of final report to be distributed to all participants and main commissions by June 1, 1957.

(e) All comments on draft of final report to be sent to each member of the task group by June 20, 1957.

(f) Meeting, if necessary, of task group July 1, 1957, to prepare final report.

(g) Final report to U. N. Scientific Committee (with copies to participants in the study and members of main commissions) before September 1, 1957.

[ICRP/56/44, ICRU/56/27. Reference: ICRP/56/43, ICRU/56/26]

Memorandum Regarding Resolution of U. N. Scientific Committee on the Effects of Atomic Radiation

1. INTRODUCTION

The U. N. resolution invites the two Commissions—

"(a) To consider and discuss the question of how to arrive at reliable data indicating the doses to different parts of the body (particularly the gonads) received by individuals and, in the aggregate, by large population groups due to the medical use of ionizing radiations, and

"(b) To examine what recording system, if any, is at present feasible for the determination of the relevant dose values, and

"(c) As a result of these studies, to submit to the Scientific Committee on the Effects of Atomic Radiation as soon as possible, and in any event before September 1, 1957, a report upon their deliberations and conclusions on the subjects (a) and (b), and to make any appropriate recommendations."

2. SCOPE OF PROBLEM

The problem resolves itself into three main aspects:

(a) The doses to the gonads of patients;

(b) The doses to other organs of patients;

(c) The occupational exposure of all those using, or in the vicinity of, sources of ionizing radiation in medical and allied fields.

It is considered that by far the most important of these aspects at the present time is (a) and this receives most attention in what follows. It is assumed that both diagnosis and therapy are involved and that by medical use is meant not only the patients of radiologists but also those other medical practitioners, dentists, osteopaths, chiropractors, etc., and also patients undergoing diagnosis and therapy with radioactive nuclides.

It will be possible to extend the scope of the inquiry to include other organs and also to include occupational exposure once the main problem has been dealt with.

3. THE DOSE TO THE GONADS OF PATIENTS

This dose is specifically of interest because of its genetic significance, and in consequence, only the irradiation of persons who are likely to become parents is of importance..

(a) Diagnostic radiology

The following information is required for a proper assessment of the significance of doses to the gonads:

(I) The vital statistics of the population as regards mortality, the ages at which both males and females become parents, and also the average number of children born to each parent.

(II) The number and types of radiological examinations, both radiographic and fluoroscopic, and with radionuclides, performed on both sexes as a function of age up to the age of 50, which would include the number and types of examinations performed on pregnant women (in which both the parents and the foetus are involved).

(III) The doses delivered to the gonads of each sex (and to the foetus where involved) during each type of examination, both radiographic and fluoroscopic and with radionuclides.. These doses are liable to vary in different hospitals and disciplines and will also depend on the size of the patient, e. g., whether infant or adult.

The combination of the information referred to in 3 (a) (I)–(III) above, weighted where necessary to allow for the fact that the individuals undergoing certain types of examination, e. g., hysterosalpingography, may be abnormal as regards expectant parenthood, permits an assessment of the genetically significant dose to be made.

(*b*) *Therapeutic radiology*

This requires essentially the same treatment as that of diagnostic radiology. Therapy with radionuclides includes teletherapy, interstitial and intercavitary insertions and also the injection or ingestion of radioactive solutions and the like. These various types of therapy involve the gonads in different ways and would need to be assessed separately.

It should be noted that in the case of therapy, the character of the disease may affect the probability of the patient subsequently becoming a parent.

(*c*) *Methods of obtaining the data*

The genetically significant dose may be obtained for a particular country in a variety of ways:

(I) By keeping records of the radiological exposures of all individual members of the community up to the age of 50;

(II) By obtaining statistically adequate samples of the items referred to in 3 (a) above as applied to both diagnosis and therapy;

As far as 3 (a) (I) is concerned, the necessary data are available in many countries as population statistics. 3 (a) (II) may be obtained either by taking a sample of institutions and installations of all types and examining the techniques and patient records, or by taking a random sample of the population and studying their X-ray diagnostic and therapeutic experiences during a specified period. The data referred to in 3 (a) (III) requires evaluation for the variety of conditions that arise. Existing information on this subject is extremely meager and further studies are urgently required. If a limited sample of the population is studied, it may be possible to evaluate the doses from direct measurements on each patient.

(III) In some countries, information as to the statistics of diagnostic and therapeutic radiology can be obtained from the records of health insurance companies and similar organizations. It is considered that the records of these organizations will include details a sto age, sex, type of examination, etc.

(IV) An indirect approach, which would provide an assessment of the amount of diagnostic radiography carried out, could be made by obtaining from the suppliers and/or manufacturers of X-ray films the total quantity of films supplied for medical purposes in a country during any particular period. Such information, combined with more detailed information obtained possibly in another country by methods 3 (c) (I) or (II) would enable a rough estimate to be made of the relative quantities of radiography in the two countries concerned. No information would be obtained by this means regarding the relative amounts of fluoroscopy or therapy, and we have reason to believe that these vary considerably from country to country. In consequence, the approach suggested in this section would lead only to a very approximate assessment of the total significant gonad dose.

(V) Another possible indirect method of obtaining relative data from which assessments could be made is to obtain information from the manufacturers and/or suppliers of X-ray tubes regarding the turnover of tubes of all types in the country concerned. This would provide a rough estimate of the total X-ray tube loading, which would then have to be combined with statistical data regarding the average gonad dose per unit of tube loading. Although very approximate, the figure derived in this way would include both radiography and fluoroscopy and possibly X-ray therapy as well.

(VI) A further possibility of obtaining a rough estimate of the extent of the gonad dose would be to keep records of the use to which X-ray diagnostic and therapeutic equipment is put. At the present time, this is not regarded as a practical approach, but if all diagnostic X-ray apparatus (in particular) were fitted with a method for registering the total tube load in milliampere-minutes, both for radiographic and fluorscopic work, the information thus obtained, combined with data of a statistical nature as to operating voltage, focal distance, etc., would again permit some relative data to be obtained. An alternative procedure would be to fit each tube with an integrating chemical dosimeter and thus determine directly the dose delivered to an arbitrary point, from which calculations as to the gonad dose could proceed. An approach to the

manufacturers of X-ray apparatus is recommended in connection with these suggestions.

(VII) As far as the internal use of radionuclides is concerned, it is thought that their contribution to the gonad dose is small at present. However, an assessment could be made, starting from the data which are commonly available, on the quantities of such nuclides which are supplied in each country for medical purposes.

(VIII) Details of the distribution of examinations and treatments in terms of age and sex may be most readily obtained by enlisting the assistance of national medical and similar societies. For this purpose, such societies could circulate their members with a questionnaire of an approved type and furnish the data to the commissions or to a national representative of the commissions.

4. THE DOSES TO OTHER ORGANS OF PATIENTS [1]

Detailed consideration was not given to this aspect of the problem during the informal meeting of the two commissions in New York. It is obvious that any particular organ or organs can be dealt with in a similar manner to that outlined for the gonads, once the investigation into average organ-dose versus skin-dose has been completed. However, the skin itself is one of the organs of importance, and in this case it appears desirable to estimate the aggregate dose to each part of the skin having an area in excess of the "significant area" of 1 cm^2.

It is clear that an attempt to obtain records or data on this aspect of the problem would assume enormous proportions unless the number of organs selected for investigation were to be strictly limited; and it is suggested, at the outset, that consideration be given to the "critical organs" specified by ICRP for protection purposes. These are (apart from the gonads) the skin, the blood-forming organs, and the iris (lens).

It is important to note that where those other organs are concerned, the maximum dose likely to be received by an individual is the primary consideration, although doses averaged over the community might be of interest as regards effects that are only detectable statistically. In these circumstances, if it is decided to keep records, it would not suffice to confine them merely to age and sex. Sampling procedures would also have a rather restricted value.

5. OCCUPATIONAL EXPOSURE OF ALL THOSE USING, OR IN THE VICINITY OF, SOURCES OF IONIZING RADIATION IN MEDICAL AND ALLIED FIELDS.

It is not clear whether or not the U. N. Committee intended to include this subject in the study. However, it is of sufficient importance to merit some consideration, although the contribution to the aggregate gonad dose of the population is at the present time relatively small. Provided the recommendations of ICRP are followed, the dose to the gonads received from occupational exposure up to the age of 30 (the approximate mean age of reproduction) will not exceed 50 rem. The injected dose from those occupationally exposed will therefore not exceed 50 rem multiplied by the number so exposed. To this must be added the dose received by those persons in uncontrolled areas around each installation, where the recommended dose in 30 years would not exceed 15 rem (5 rem per decade). It is highly probable that, although this latter group might be larger than the occupationally exposed group, the injected dose would be less, and thus the total injected dose will be less than twice the dose received in controlled areas.

From the point of view of the population, the study should not be compared to the medical and allied fields, but should include all sources of occupational exposure; and it is suggested that the evaluation of the total injected dose due to the occupational use of ionizing radiation be given consideration in all the countries concerned in the main study.

In this connection, the keeping of formal records is a much less formidable problem than for the general population, and is beginning to be considered a worthwhile undertaking in order to insure that the limits set for exposure up to the age of 30 and for each succeeding decade are not exceeded.

[1] Secs. 1–3 of this memorandum were approved by an informal joint meeting of ICRP and ICRU in New York, November 1956. Secs. 4–6 were prepared by the acting secretary of the ICRP at the request of the meeting, and have not been reviewed by the Commissions.

6. IMPLEMENTATION OF THE STUDY

Document ICRP/56/43, ICRU/56/26 outlines the scheme prepared during the joint meetings for implementing the study. Briefly, the study is divided into 5 tasks, each the responsibility of a person selected by the joint Commissions. These tasks are as follows:

Task 1. The coordination of information regarding the gonad dose for males and females in terms of skin dose for each type of X-ray or γ-ray beam therapy. Also, the coordination of information relating to the average skin dose and doses to other organs of the body during such examinations and treatment.

Task 2. The coordination of information regarding the possibility and merits of the complete recording of the radiological history of the whole population—

(*a*) for each individual;
(*b*) for each age group and sex.

This study is to include the cost and the effort required for this complete recording.

Task 3. The coordination of information regarding various methods of sampling, e. g., of individuals, of installations, of professional people.

Task 4. The coordination of information regarding the possibility of using approximate methods, e. g. data supplied from health or social security agency records; film supplies; X-ray tube turnover; recording total exposure of X-ray tubes; integrated dose measurements; questionnaire of professional people.

Task 5. Coordination of information regarding the doses delivered by the use of radionuclides directly injected or ingested in the body, both for the diagnostic and therapeutic purposes.

National leaders for some countries have been selected and others are being sought from among the members of the two Commissions. In addition, the radiological societies of those countries affiliated to I. C. R. and not covered by the above are being approached. In this way it is hoped to initiate studies in a large number of countries, which will be coordinated by the Commission task leaders. Arrangements have been made for a full exchange of information between the various persons concerned and it was considered that the work would be considerably facilitated if each of the Commission task leaders prepared a brief memorandum outlining his own particular task for the benefit of the national leaders.

As the time available for the study is very short, a time table has been worked out which it is essential to follow. The whole study will be coordinated by the Secretary of ICRP,[3] to whom any requests for further information should be addressed.

APRIL 19, 1957.

UNITED STATES TASK REPORT ON ICRP/ICRU/UN STUDY

THE PROBLEM

During the New York meetings of the ICRP/U in October-November 1956, the Commissions were invited by the U. N. Scientific Committee on the Effects of Atomic Radiation—

(*a*) To consider and discuss the question of how to arrive at reliable data indicating the doses to different parts of the body (particularly the gonads) received by individuals and, in the aggregate, by large population groups due to the medical use of ionizing radiations;

(*b*) To examine what recording system, if any, is at present feasible for the determination of the relevant dose values; and

(*c*) As a result of these studies, to submit to the Scientific Committee on the Effects of Atomic Radiation as soon as possible, and in any event before September 1, 1957, a report upon their deliberations and conclusions on the subjects (*a*) and (*b*), and to make any appropriate recommendations.

---

[3] Mr. W. Binks, director, Radiological Protection Service, Clifton Avenue, Belmont, Sutton, Surrey, England.

In the following, the discussion applies primarily to the gonadal dose, but it is understood that the same arguments apply to the dose to other parts of the body. The problem, of course, becomes more complex for multiple organs, whole body or integral dose, bone marrow, etc., in ascending order.

In order to complete this project and to spread the work out as much as possible, the two Commissions at that time decided to divide the work into five tasks.

Task 1. General: Gonad dose versus skin dose and average dose per examination.
Task 2. Complete recording for entire population.
Task 3. Sampling procedure.
Task 4. Approximate methods:

(*a*) Health and social security agency records.
(*b*) Film or X-ray tube records.
(*c*) Questionnaire to professional people.

Task 5. Dose from unsealed radionuclides.

The first deals with the determination of the dosimetry factors (dose to the gonads per unit skin dose or per examination of the different types); the next three deal with methods of arriving at statistics either on the number of examinations on, or the skin dose to, the population from different diagnostic and therapeutic applications of external radiation; the fifth deals with the gonadal dose from diagnostic and therapeutic applications of internal irradiation.

During a meeting of the United States task leaders in New York on March 19, 1957, the problem was further discussed and the following position stand taken:

RECOMMENDATIONS

1. In view of the attainable accuracy and the significance of the final results by any method, it is considered that the most useful immediate method for obtaining an estimate of the total gonadal dose to the population would be through the use of *indirect statistical sampling.* Parameters in this sampling include film consumption, number and types of X-ray machines, number of users,[1] distribution of types of examinations, published data on gonadal dose, etc. The results in the report by Laughlin and Pullman on the estimated gonadal dose to the United States population from the medical use of X-rays was arrived at by the methods considered independently at the October-November 1956 meeting of the two Commissions. The outstanding factors which make the final results uncertain include (1) the variation in the gonadal dose per examination for different users and in certain types of examinations such as fluoroscopy plus weighting errors in age and procreative potentiality, and (2) the actual number of examinations performed by each group of users. The former, (1), probably produces the greater uncertainty in the final results; the latter, (2), may be somewhat indirectly checked by, for example, the number of films sold. Presently published results of data on gonadal dose probably represent the best that can be done without a major effort to improve the overall accuracy of the input data. The elimination of some data of dubious value and the addition of new data from types of users that have not been adequately sampled could possibly result in some improvement of the final result by this technique. However, such results would have to be tested for statistical adequacy.

Until there is much better knowledge of the gonad dose in relation to specific type of examination, there seems to be little point in the employment of more elaborate and more costly evaluation procedures. For purposes of determining the future trend (increase or decrease) of the population gonadal dose by this sampling method, it would probably be necessary to introduce some relatively simple record procedures to improve the significance and accuracy of the results.

2. It was agreed that a preferable method of arriving at the gonadal dose is by *population sampling.* This could best be done by determining the gonadal dose administered by a representative sample of the users of radiation. Such a survey should probably also include a sampling of the recipients of the radiation to determine if, in the future, information obtained from them would be of value. Sampling would include not only the distribution of examination types but also the actual dose delivered to the gonads from each examination. No

[1] By user is meant the person applying radiation to a patient for medical purposes.

attempt would be made to do this on a name basis but rather on an age basis. It was also recognized that the investigation itself would encourage improved procedures resulting in a reduction of the gonadal dose, and this would make uncertain the dose that had been delivered prior to the investigation. However, this reduction was considered more important than the determination of the dose given in the past.

A full-fledged sampling program, of course, should be preceded by several trial sampling programs. Population sampling does not have to be continuous but should be periodically repeated. The change in the dose during intervening periods might be adequately estimated from data on supplies such as films, X-ray tubes, etc. This may be worth doing even if the larger sampling program does not prove to be economically or technically feasible as learned on basis of trials.

3. From the point of view of bringing about a desirable decrease in population dose, it is believed that direct efforts toward this end would be most profitable. This can be accomplished best by educating the user rather than by alarming the patient. Educational procedures would include such items as:

(*a*) Preparing and circulating through professional channels suitable information on good radiologic practices.

(*b*) Including in medical school curriculums adequate instruction on radiation effects and on improved radiologic practices and procedures.

(*c*) Providing information and guidance that emphasizes the need for judgment in respect to the indications for radiologic diagnosis and therapy in relation to possible radiation hazards; in other words, develop an awareness of the need to balance carefully the health benefit against the possible risk to either the individual or the race.

Concurrently, there should be additional study and research on:

(*a*) Methods and techniques for performing radiation diagnostic procedures with less exposure of the patient generally and the gonads in particular.

(*b*) Development of new apparatus and techniques that will provide the requisite diagnostic results with minimum patient exposure.

(*c*) Establishment of more reliable data on the relationship between gonad (and other organ) dose and given types of diagnostic procedures.

(*d*) Development of improved methods and apparatus for measurement of radiation dose, particularly during fluoroscopic procedures.

REMARKS ON OTHER MEANS FOR EVALUATING POPULATION DOSE

Task I

4. Before any precise evaluation of gonadal dose to the population can be made, certain new basic studies will be necessary. Analysis of existing data has yielded about all the information possible; at this point most past information might as well be disregarded. Acceptable procedures and instrumentation must be established and evaluated for practical application in determining gonad dose under the wide variety of conditions encountered in medical practice. Statistical analysis of the results must be proven by actually working with suitably sized patient samples. Field studies will be necessary.

For many radiographic procedures the problem is relatively simple, but for some the problem can be quite difficult. For fluoroscopic procedures it will be extremely difficult to determine the gonadal dose under "average" conditions, as this involves so many personal factors that will vary widely between physicians, between different patients when something abnormal is found, etc. Until these studies can be completed (probably many years, if ever), there is little point in setting up elaborate and costly recording systems. It is possible that as a normal consequence of these studies such improvements will develop as to eliminate the supposed need for recording.

Task II

5. An attempt to determine the dose to each person of the population, either by name or by age group, is not considered feasible for the United States for such a system would have to depend upon the users of the radiation reporting accurately the dose received. This cannot be done accurately because (1) the gonadal dose per examination is not accurately known, and (2) only a very small percentage of significant returns would be anticipated. This anticipation is

based upon results of surveys covering items that are much easier to report. Because of the small percentage of good returns expected, the results of such a study may be badly biased in the direction of the procedures used by the more conscientious reporters.

6. No system or plan for universal recording of the gonadal dose of the whole population is considered as desirable or feasible, certainly for the foreseeable future.

(*a*) Complete recording by individual and age groups:

Basic gonad dose data is lacking;
Cost is excessive;
Purpose is questionable;
Genetic analysis in future is uncertain (10 to 20 generations of data needed);
Method is unnecessarily complicated, if only to determine population gonad dose;
Accuracy is no greater than from simpler methods.

(*b*) Recording by age groups only:

Basic gonad dose data is lacking;
No way to adequately collect and utilize records so kept;
Loss of records would destroy statistical value;
Self-carried cards may have adverse psychological effect on individuals.

Task III

7. Certain types of sampling procedures may be of value and will assist in providing some of the necessary data on gonad dose. (See par. 2.) These procedures must not be entered upon hastily. A full-fledged population sampling program must be preceded by several trial sampling programs. It is quite possible that, in time, a suitable sampling may be developed such that if repeated, say, every 10 years, the trends of population dose may be determined. A check every 10 or 20 years should be adequate for control purposes. Development of a reasonably adequate sampling procedure for the United States might cost of the order of $300,000 per year for 5 years. Once developed, a population sampling procedure might replace the indirect statistical sampling procedure outlined in paragraph 1.

Task IV

8. Approximate sampling methods have been recommended for use in estimating the total gonadal dose of the whole population.

(*a*) Health and social security records have a limited usefulness; by themselves they will not provide the information needed.

(*b*) Film sales provide one useful source of information on the radiographic load in this country.

(*c*) X-ray tube records are of little value in arriving at the dose administered.

(*d*) X-ray apparatus records will provide some useful information.

9. Some estimates of the gonadal dose to the population may be made by means of questionnaires sent to radiation users through their professional organizations. Experience with questionnaires in other connections indicates that their effectiveness may be doubtful for various reasons:

(*a*) Basic data on gonadal dose is lacking;
(*b*) Reporting will be too careless;
(*c*) Returns will be small and are likely to be biased by data submitted by the more conscientious reporters.

Task V

10. The gonadal dose from unsealed radionuclides is inconsequential at present.

[Task 1, United States]

RECOMMENDATIONS FOR PLAN OF STUDY OF TASK 1 WITHIN THE UNITED STATES, UNDER UNITED NATIONS' SCIENTIFIC COMMITTEE ON THE EFFECTS OF ATOMIC RADIATION

Task 1 is concerned with the procurement of data on the gonadal dose received during medical diagnostic and therapeutic X-ray procedures. In the outline of study by the ICRP, task 1 is 1 of 5 tasks slated for investigation

by the U. N. Scientific Committee on the Effects of Atomic Radiation. Tasks 2, 3, and 4 are also closely related to the problem of radiation dosage during medical X-ray procedures. Task 1, however, is primarily concerned with dosimetry, whereas tasks 2, 3, and 4 are primarily concerned with statistics. For example, E. E. Smith, international commission leader for task 1, cites in his instructions to national task leaders that task 1 is concerned with the development of "a set of factors which gives directly the average gonad dose for each type of examination." Smith then goes on to state that "when the table of factors has been obtained, it will be possible, by combining them with details of numbers of examinations of each type in terms of age and sex, to assess the aggregate genetically significant dose."

Although task 1 is primarily concerned with dosimetry, there is a major statistical aspect involved in it. For example, the dosimetric values obtained in task 1 will be greatly reduced in value unless they have been obtained on subjects who are representative of the general population receiving diagnostic or therapeutic exposure. It is therefore strongly recommended that, at the outset, there be established for the United States task force, at least, an advisory committee consisting of a biostatistician, an epidemiologist, a geneticist, a physicist, and a radiologist to coordinate the efforts undertaken within the various tasks.

To illustrate the need for such an advisory committee still further, attention is called to a study to be undertaken soon under the Radiation Study Section of the National Institutes of Health in which a statistically wide range of individuals of varying physical types will be studied dosimetrically for gonadal dose. More will be said about this study a little later. However, it will be quite clear that unless tasks 2, 3, and 4 provide data of the range of body types which are expected in the various age and sex groups, the dosimetric study will be greatly reduced in value. As far as the United States is concerned, I do not know how an advisory committee of the type suggested can be financed. However, unless an advisory committee with representation of the several disciplines which have been recommended is established, this study is likely to progress little further than previous studies.

It may be argued that the various task leaders may seek, at their discression, consultation in statistics, epidemiology, genetics, etc. However, such consultation does not provide the unifying force which is needed for the various task leaders to proceed most effectively.

As far as the procurement of gonadal dosage data is concerned, one may proceed in several ways. Before any of these is discussed, it may be well to outline the major variables which influence the gonadal dose following a diagnostic or therapeutic procedure. These factors may be divided into four principal groups:

(*a*) Patient factors:
(*b*) Procedural factors;
(*c*) Equipment factors; and
(*d*) In the case of fluoroscopy, professional factors.

Under patient factors, sternal-public distance and anatomical thickness perhaps are two of the principal variables. Under procedural factors, field location, field size, anatomical projection and beam angulation constitute some of the principal variables. In regard to equipment, kilovoltage, filtration, and generator wave forms are three important variables. In regard to the professional variable of fluoroscopy, marked variation occurs, of course, between one physician and another.

From the large number of variables set forth in the preceding paragraph, it is quite clear that the procurement of data for the fulfillment of task 1 necessarily is quite complex. A number of investigators have suggested that these data may be obtained by dosimetric measurements on a large population group involving many hospitals and physicians' offices, sufficient to obtain statistically significant values through the range of radiographic, fluoroscopic and therapeutic procedures normally encountered in medical radiology. Such a study, however, seems enormously costly, and, furthermore, much of the work involved in this type of investigation would be concerned with work carried out by the remaining tasks 2, 3 and 4. Furthermore, when all of the data under such a plan would be at hand, they would tell little more than what the dosage values have been under past circumstances. They would not be particularly valuable in the estimation of the gonadal dose under future conditions. Perhaps, most important of all, they would not be too valuable in the development of a set

of standards of radiologic procedure which the medical profession in the future might follow to insure minimum dose to the gonads.

The establishment of a set of standards of radiologic procedure seems very important from a number of aspects. First, from the data supplied by the British and United States Committees, presented late in 1956, it appears that the gonadal dose of the general population during the significant reproductive period of life, is of the same order as the dosage received from background radiation. A perusal of the radiologic literature during the last several years indicates that radiologists have not been greatly concerned with the maintenance of minimum dosage to the gonads and hence there is some reason to believe that, by a well-regulated set of standards of radiologic procedure, the gonadal dose of the general population might be reduced to a relatively small fraction of that received from background radiation. Therefore, it appears quite clear that, if at all possible, the data obtained under Task 1 should be of a type which is not only useful in telling what the gonadal dosage has been in the past, but what procedures and regulations might be developed in the future to reduce substantially the gonadal dose in medical radiologic procedures and yet retain all of the benefits that these procedures yield.

The studies, referred to above, to be undertaken under the auspices of the Radiation Study Section of the National Institutes of Health, appear to be of a type which will accomplish just such objectives. In this study, a statistical representative group of subjects will be irradiated through a wide range of kilovoltage, filtration, and wave form, and with the data recorded in such a manner that gonadal dose may be readily determined for essentially a continuous range of field sizes and field locations. In this study, considerable reliance will be placed upon computing techniques. The data will be collected also in such a manner that, as new techniques develop in the future, they will provide ready assessment of the dosage conditions under these new techniques.

It is not implied from the foregoing that the techniques to be followed under the Radiation Study Section investigation are the only ones which should be investigated in the United States. Indeed, the Advisory Committee, referred to above, may well determine that a number of other studies should be pursued. However, it appears quite desirable that whatever studies are followed, their ultimate objective should not only be the procurement of dosage data under present-day conditions, but also data in such a form that ultimately, within a short time, there may be established a set of standards of operating procedure in radiology which may be adopted and employed by physicians everywhere to insure that the gonadal dose in medical radiology to the population at large is substantially below that received from background radiation.

RUSSELL H. MORGAN, M. D.

FEBRUARY 25, 1957.

[Task 2, United States]

COSTS OF RECORDING PROCEDURES (TO THE PHYSICIAN)

To obtain some rough idea of the cost to the medical profession (and hence to the patient) of a central recording system, the attached forms were submitted to two radiological groups for study. One group was a moderately large private office, and the other a hospital clinic. Each was known to have good cost-accounting practices.

Estimates from both were essentially the same. Costs were based on a daily load of 50 patients, thus making it possible to use quantity recording techniques.

Use of either form A or form B would be about the same. While the former calls for more individual record forms, the latter requires the same information and, in addition, necessitates a sorting process to group the irradiations in the proper category. It was thought that if a cost difference were to develop, the form B would be the more costly.

For a daily workload of about 50 patients, the *minimum* cost of recording and reporting the examinations or treatments would be about $0.30 per patient. For patient loads of less than 10 per day, the probable minimum cost would be about double, or $0.60 per patient.

If it were required to estimate the gonad dose for each patient the costs would be substantially larger if it was necessary to estimate any closer than within a factor of 2 or 3. This is based on current practices, equipment, and techniques.

Costs might be lowered somewhat, if in the future, suitable instrumentation techniques were made available—provided the instrumentation is not too costly.

L. S. TAYLOR.

Various proposals relative to the recording of the medical exposure of the whole population are being studied. We are now concerned with the cost of this to the physician, from the point of record keeping and reporting to some central agency.

Attached are two sample forms.

Form A would be filled out in triplicate for each patient, and copies of all forms sent in weekly to the central agency.

Form B would be filled out weekly and sent to the agency. This would group all exposures together by age, type of irradiation, and in the case of therapy, the dose. In essence this gives the total dose delivered per week by the physician, but is not associated with any individual patient.

For conditions in your office will you please estimate the number of man-hours per week and the cost that would be required for filling in and submitting form A? Form B? What would it cost per year to maintain your own permanent records and copies of the same?

For purposes of comparing costs where large and small numbers of patients may be involved, it is necessary to relate these to the approximate weekly patient load.

Do not be concerned about the particular sample forms attached. They are admittedly inadequate, and are designed mainly to show the number of entries.

FORM A

Information needed (for individual report):
Name:
Address:
Age:
Date:
Sex:
Social security number:[1]

1. Radiological examination:
   (a) Radiographic:
       Region
       Film size
       Number of films
       K. V. P.
   (b) Fluoroscopic
       Region
       Ma-sec
       K. V. P.
2. Therapy: State dose and region.
3. Instructions: Send 1 copy to agency, 1 copy to patient, and retain 1 copy.

FORM B

Information needed (weekly group report):
1. Radiographic (age: 9 months to 30 years).
   Number of exams by type (probably about 20 types):
       Head
       Neck
       Chest
       Heart
       G. I.
       Extremities, etc.
2. Radiographic (age, over 30 years) (same types).
3. Fluoroscopic (age, 9 months to 30 years):
       Number of milliampere minutes by type of examination (probably about 8 types).
4. Fluoroscopic (age, over 30 years) (same types).
5. Therapy: Give total dose (skin) by regions (probably about 10 regions).

[1] If person has no social security number, provided necessary application forms and submit same within report.

[Office memorandum]

UNITED STATES GOVERNMENT,
BUREAU OF THE CENSUS,
April 1, 1957.

To: Dr. Lauriston S. Taylor, Chief, Atomic and Radiation Physics Division, National Bureau of Standards.
From: Morris H. Hansen, Assistant Director for Statistical Standards.
Subject: National radiation registry.

This relates to your memorandum of March 18 and our telephone discussions as well as your conversation with Mr. McPherson of our Bureau.

We have estimated only very rough order-of-magnitude costs. Our estimates can be viewed, we believe, as minimal since we have assumed that the most modern (in terms of present art) equipment can be used. Particularly important is our assumption that manual transcription of information on report forms will not be necessary. Instead, we assume that Fosdic report forms could be used. As you know, Fosdic scans microfilm copies of reports and transcribes the intelligence recorded on the form to magnetic tape.

Our approach contemplates continuous processing of the reports through the microfilming operation and periodic processing of the rolls of microfilm through Fosdic and an electronic computer. We arbitrarily decided that the Fosdic and computer work might occur 4 times every 10 years. Unless the microfilming is kept current the accumulation of reports would constitute a tremendous storage problem.

We estimate that between 35 and 50 million dollars would be required to defray the cost for the first 10 years of the method we visualize. Most of this would be spent at a rate of 2½ to 3½ million dollars per year to defray the cost of microfilming and the work precedent to microfilming.

About $6 million would be required to buy microfilm cameras, Fosdics, and magnetic tape. We have not included the capital cost of electronic computing equipment. Instead we have assumed that equipment owned by the Government would be available when needed. The only computer costs we have included are the operating and maintenance costs for 3 computer years to be used 4 times per decade. These are estimated to be from $300,000 to $500,000 each of the 4 times we have assumed they would be required during a decade.

Broadly described, the plan we used to make these estimates would be operated as follows:

Steps 1 to 3 below would be continuing work:

1. The reports, both individual and weekly group reports, would be designed using a Fosdic format. We believe all the information you describe with the exception of name and address could be recorded so that a Fosdic could read it.

2. A. The individual reports would be manually processed through a name-coding operation in which 3 or 4 significant characters of surname would be recorded in a manner amenable to reading by Fosdic.

B. The weekly reports would also be manually coded and edited prior to microfilming. The details of this process would have to be worked out. Our estimate makes allowance for some premicrofilming work.

3. Microfilm the reports.

Steps 4 and following would be prosecuted when the necessary electronic computer time was available.

4. Transcribe from microfilm to magnetic tape through Fosdic.

5. For individual reports match each report against a master list showing social security number and name. Note here that the 3 or 4 letters of surname coded in accordance with 2A above would be used to isolate problems for special handling.

6. Update a master file on which—

(*a*) For individuals—the exposure history for each different person would be summarized.

(*b*) For groups—a similar summary would be made.

Obviously, we have only a sketchy picture of the job to be done. To make firm estimates a much more detailed job of planning would be necessary. A few of the considerations neglected completely in our estimate are:

1. How critical a review of the original reports is necessary? Obviously, if high standards are imposed there would be a lot of communication with original reporting sources. On the other hand, an attitude that says we'll do the best we can with what we get, can practically eliminate the need for

checking back with the original reporter. Of course, costs are affected by the policy established here.

2. How much will it cost to obtain a file on magnetic tape giving social security number and name? Our estimates assume that such a file could be made available at essentially no cost.

3. From the point of view of long-range use is name of person adequate? Would names of parents, spouse, and issue be necessary to facilitate analyses of a genealogical nature? We have completely disregarded these questions.

Our efforts to prepare estimates for you lead us to the following question which you may want to consider.

> In view of the long-range objectives of a national registry of radiation exposure should our generation attempt to do anything more than storage of information in a form we hope would be useful to future students of this problem?

Perhaps the most that should be attempted now would be a plan to store microfilm copies of forms containing information such as you describe. We might very well leave to the future the task of deciding how to process such information. As indicated above something of the order of 2 to 4 millions of dollars per year would in our opinion, defray the cost of the preparation of such microfilm.

[Task 2—ICRP/ICRU]

Complete Radiation Exposure Recording for the Entire Population

Feasibility Study for the United Nations Scientific Committee on the Effects of Atomic Radiation

The feasibility of recording the radiological history of the entire population of the United States was examined and will be discussed below in terms of the following three systems:

A. Centralized recordkeeping of the total radiation exposure identified by individual.

B. Centralized recordkeeping of the total radiation exposure by groups without identification of the individuals.

C. Radiation exposure record keeping by means of records carried by the exposed individual.

The general nature of the first system is probably self-explanatory. Although final details were not developed, it was visualized that a system resembling, at least in broad outline, the current old-age and survivors insurance (social security) recording system in use for over 100 million individuals in the United States today, could be developed.

The second proposal would be similar except that no attempt would be made to keep a record of radiation exposure by individuals, but rather the total exposures would be recorded by groups selected in such a manner as to provide the desired data regarding the probability of reproduction.

The third system implies that each individual would carry a card or other type of record on which could be recorded his radiation exposure each time it occurs.

A problem common to any system is related to the lack of knowledge, by many practitioners of the healing arts, of the actual dose delivered in any particular examination or treatment. A solution to this problem is assumed to be a responsibility of task 1, but is mentioned here in order to emphasize that any of the above three systems, even if feasible in all other regards, could not be put into effect pending the completion of at least a major portion of the activities involved in task 1.

A. Centralized recordkeeping of the total radiation exposure identified by individual

Assuming that task 1 were sufficiently well completed to make the data reasonably available, this system of recordkeeping theoretically should provide information regarding the radiation exposure of any individual in such a form that it could be utilized for followup studies of a research nature, and be susceptible to relatively simple tabulation of information concerning the average radiation ex-

posure of groups of individuals with any given probability of reproduction. The problem was explored primarily with the assumption that the magnitude of the task would be such as to preclude the possibility of recording exposure data other than that to the reproductive organs. It was further assumed that the advantages of this system, as compared to system B, would be lost unless actual data concerning each individual exposure (rather than average figures for typical examinations under typical circumstances) were available. It appeared that the procedure most likely to be feasible would involve the design and distribution, under the supervision of a central repository, of exposure record cards which would be coded in such a manner that for each individual radiation exposure it would be necessary to indicate only the following information:

1. Name of individual
2. A serial number
3. The amount of radiation exposure to the gonads

The card might be prepared in such a manner that the information regarding dose could be indicated by filling in a printed circle on the card corresponding to the proper code. If an individual card were prepared for each exposure, all cards could be mailed to the central repository where the necessary tabulation would be accomplished automatically by tabulation equipment, or more likely by "magnetic memory." Based on the assumption (which checks reasonably well with the data in the report entitled "Gonadal Doses Received in the Medical Use of X-Rays" prepared for the genetics panel of the National Academy of Sciences by Drs. J. S. Laughlin and I. Pullman dated November 19, 1956) that there would be approximately 100 million individual exposure items reported annually, and the further assumptions that reports would be received from approximately 100,000 reporting entities (practitioners, hospitals, etc.) and that there would be 5 million requests annually for information, these requests requiring only a statement of total accumulated exposure of an individual to date, the Bureau of Old-Age and Survivors Insurance has estimated that the cost to the central recording office would be approximately between $8.5 million and $15 million per year. To be possible in operation, the system could not keep exposure data current on a day-to-day or even week-to-week basis. It would therefore not be usable in determining the total exposure including that from recent series of examinations, as a basis for deciding the desirability of any particular proposed exposure. This estimate does not include the cost to the reporting entities of preparing and submitting the data. The cost of this latter item is not susceptible to accurate estimate because of lack of valid data.

Following informal discussions with practicing radiologists, it seems fair to assume, however, that the additional expense involved would not be sufficiently great to significantly affect the cost limits set forth above for the central operation alone. Although the cost factor to the reporting entities may be relatively small, the impact on these entities of requiring such reports would be by no means insignificant. Thus, although the workload added to the reporting entities is such that it would probably not require the addition of personnel for the sole purpose of handling this problem, except in relatively large installations, the burden of preparing these reports, no matter how simple it might be, when added to the other recording problems inherent in the clinical practice of radiology, whether by radiologists or nonradiologists, might well be great enough to seriously affect the completeness and accuracy of reporting and thus the completeness and accuracy of the final data.

The cost estimate indicated above does not include an item to cover the assignment of identification numbers. Almost all working males and the majority of those females who are gainfully employed presumably already have assigned to them a social security number which could be used also for the purpose of radiation record keeping. Since a large portion of the population has or will have such a number assigned irrespective of whether or not a central radiation exposure recordkeeping system were established, it was felt justifiable not to charge the cost of this item, for purposes of this discussion, to radiation recordkeeping. At the same time it must be recognized that there are millions of people who would be required to obtain an identification number for radiation exposure records and who would otherwise not find such a number necessary. It is obvious, too, that in most cases the need for a radiation exposure number would occur in an individual's lifetime prior to his need for a social security number. In fact the feasibility should be explored of assigning to each individual at birth a number which could be used as needed in the future.

In considering its feasibility, it is essential to take into account the probable errors in this system. In addition to those errors which will inevitably be

introduced by lack of complete or accurate data in all cases, the degree of error depending upon the completeness and accuracy of Task 1, the most obvious source of error is related to incompleteness of reporting. Although it appears possible that with proper controls the completeness of reporting might be such that the data would be usable for determination of average exposures, it also appears likely that in many cases the data would not be sufficiently complete to be satisfactory as a record of exposure to individuals. Thus, it is likely that one of the principal theoretical advantages of this system would not exist in practice. Data in situations which might be considered reasonably comparable are not available. However, it has been found, for example, that appreciable difficulty is encountered in obtaining complete reporting on such relatively simple matters as births and deaths. The importance of recording of this type is universally recognized. In spite of this fact, strong legal and administrative controls are necessary to maintain this reporting at a high rate. Because of the existence of these controls, which would be difficult or impossible to duplicate in the field of radiation recordkeeping, the experience with birth and death records is not considered applicable to this problem. A situation which is perhaps more comparable is that of the reporting of communicable diseases. It has ben estimated that the completeness of reporting of communicable diseases averages less than 50 percent. Even here, the situation is not considered directly comparable to radiation exposure records because of the relative simplicity of communicable disease reporting, as well as the indeterminate factor of the psychological approach of reporting entities.

It is interesting to note that the only identifying data necessary would be the name and number. The Bureau of Old-Age and Survivors Insurance has made extensive studies which indicate that the possibility that a minor error in recording the number would lead to the crediting of the data to another individual with the same name and a similar number is so remote as to be negligible.

B. Centralized recordkeeping of the total radiation exposure by groups without identification of the individuals

The system under consideration here would be somewhat similar to system A except that no attempt would be made to record the data with identification of the individual involved. Instead, the data would be recorded by groups established on the basis of reproductive probability. The task would be made somewhat complicated as there are many factors in this country which affect the probability of reproduction. The most obvious one and the one mentioned most commonly is that of age. A most important factor, and one which is often overlooked, is that of health status. To the best of my knowledge there are no data currently available concerning the degree to which radiation exposure is a function of diseases which affect reproduction, but it is logical to assume that a large proportion of both diagnostic and therapeutic radiation exposure is to individuals suffering from a disease which has an adverse effect on the probability of reproduction. There are several additional factors, such as socioeconomic status and religion, to mention but two. The number of groups necessary to maintain validity of the data would, of course, depend on the number of the variables. These would probably not have a major impact on the cost of the system in terms of the central operation, but would add to the number of factors to be coded for each exposure and thus would add significantly to the load on the reporting entities. The system, as suggested here, could probably be accomplished with the least expense and difficulty to both the central agency and the reporting entities if it were set up technically on a system similar to system A—that is with individual record cards for each exposure, but without name or identification number, and with the addition of appropriate coding for the other variables involved.

It has already been pointed out that the task of the reporting entities under the system would be approximately the same as that under system A. However, it would not be necessary to include names, but would be necessary to include additional data regarding the variables which affect the probability of reproduction.

System B could be used if the reporting entities indicated the type of examination, rather than individual dose, provided that information is available from task 1 concerning average exposure data and if it is found that the factors related to reproductive probability do not affect the average dose for any given type of examination.

The cost of maintaining a central recording agency to record statistics from group reports has been estimated to be between $250,000 and $500,000 per year. This figure includes the cost of maintaining a file of reporting entities to provide followup on the completeness of reporting.

C. Radiation exposure recordkeeping by means of records carried by the exposed individual

The success of this system would depend to a great extent on the cooperation of exposed individuals in carrying and maintaining individual exposure records. If such cooperation were complete, this system could, in theory, provide the same information obtainable under system A, except that the information would be available only to persons having access to the individual personal exposure records.

This system is dependent upon the successful completion of task 1 to the same degree and with the same accuracy as for system A. It is quite possible that the element of bias on the part of the reporting entities would be more serious under this system than under system A.

There are no data available on comparable systems that might have been used for other than radiation-exposure recording. It has been established, however, that even in the instance of such relatively simple information as immunization records, where the importance is readily recognizable, individuals do not maintain and retain records which are sufficiently complete and accurate to be worthwhile except under specialized circumstances (for example, where immunization cards are required by immigration authorities). Although health records are maintained on the military population on a fairly successful basis, this is assumed to be true only because of the strict administrative control which can be exerted in the maintenance of such records. Other experience in this same general area leads inevitably to the conclusion that the maintenance of exposure records by the individual concerned would not be of suufficient completeness and accuracy to serve any useful purpose in determination of total population radiation exposures. Realistically, it appears that such a system would be of benefit only to that relatively small number of individuals whose personal interest and concern is sufficiently high to assure that his record would be reasonably accurate.

Of the three systems proposed, this system would presumably have the least impact on the reporting entities, once task 1 were accomplished. It would require only the simplest of recording techniques. Although the exposure data to be entered on the exposure record is not currently available to the majority of the users of radiation in the healing arts, such information should be made available to these practitioners regardless of whether this or any other recording system is instituted, and therefore the cost should not be charged against the reporting system.

In addition to the obvious weakness of this system in that it would not be sufficiently complete and accurate to provide data regarding total radiation exposure of the population, there are other serious and overriding considerations arguing against its use. The first and one of the more important is that of the psychological impact on the patient if he is provided with all data regarding his total radiation exposure. There has already been some difficulty arise as a result of the recent awareness of lay persons of the potential hazard attending medical X-ray exposure. This has, in turn, led some patients to attempt to make decisions regarding the need or hazard of specific examinations. The need for any individual examination or treatment involving a radiation exposure can properly be made only by an individual in a position to balance the possible benefit against the potential harm. Obviously, the individual ordinarily in the best position to make this decision is the practitioner, and the patient is often in the poorest position to make this decision. The possibility that patients might refuse examination once an arbitrary limit of exposure (for example, 10 roentgens) has been exceeded, regardless of the beneficial or possibly lifesaving result expected, is real. It must be remembered that in many cases where repeated or extensive radiation exposure is indicated, it would be the decision of the practitioner to withhold from the patient, for his own benefit, information regarding the seriousness of his condition.

Another major difficulty in having the patient carry his own exposure card, particularly in this country, is the medicolegal one. The medicolegal hazards in the practice of radiology are already sufficiently serious that a substantial extra premium is charged for professional liability insurance covering individuals

using radiation in their practices. To provide a record to the patient which established the fact that in his case certain arbitrary limits of exposure had been exceeded would seem to inevitably lead to a large number of malpractice suits. Such suits could have a serious impact on the use of radiation in the healing arts whether or not they could be successfully defended. Perhaps an even more important implication of the medicolegal problem is the bias which it might create in the recording of the data. This point seems so obvious that further discussion is not needed.

The State radiological society which recently had the suggestion made in its name that such a system be instituted, has suspended this recommendation on the basis of a preliminary feasibility study.

SUMMARY

The feasibility of radiation exposure recordkeeping for the entire population has been discussed with agencies most knowledgeable concerning the technical problems involved and with practitioners of the healing arts upon whom the impact would be most severe. The more important considerations stemming from these discussions are pointed out above. Following is a summary of the conclusions reached regarding the feasibility of the three alternate systems which appear most reasonable:

1. System A would be possible of accomplishment when task 1 is completed in all respects, and information regarding radiation exposure under all the variable circumstances if any given examination by any given practitioner on any given patient are known. (Pending the report from task 1, it is assumed that this Utopia will not take place in the immediate future). The technical problem of centralized recording and compiling of the data is one which experience with social security records indicates could be mastered. The high probability of incomplete reporting implies that the primary aim of such a system (i. e., accurate data regarding the exposure of each individual) would not be accomplished. The expense would appear high. Equal funds expended in activities designed to reduce the radiation exposure of the population might well be of greater benefit than funds expended for recording the present status.
2. System B would appear to be possible once adequate data are available from task 1. Such data would not need to be as complete as those for either system A or C. The cost would be substantially less than for system A. The impact on the reporting entities (practitioners, etc.) would be great enough to significantly affect the accuracy of the final data. Pending reports regarding task 3, it is assumed that essentially the same information as would be obtained by this system could be obtained with better accuracy and less expense by a sampling procedure.
3. System C could not be expected to provide reasonably accurate data regarding *total* radiation exposure of the population. Although it is the least expensive of the systems discussed, consideration of the psychological and medicolegal impact make it appear not to be feasible, even if it could provide the desired data for some individuals.

It is concluded therefore, that after task 1 has accomplished at least a substantial part of its duties, complete recordkeeping would be possible, but would not be desirable, because information of essentially equal value could be obtained with substantially less expense and with probably greater accuracy on a sampling basis.

[Task 3—ICRP/ICRU]

DIRECT SAMPLING METHODS

FEASIBILITY STUDY FOR THE UNITED NATIONS SCIENTIFIC COMMITTEE ON THE TOTAL POPULATION SAMPLING

The feasibility of determining the total radiation exposure of the population by means of (1) *direct sampling of the population* as well as by means of (2) *sampling medical institutions* was studied with the cooperation and assistance of individuals and groups most intimately concerned and most knowledgeable regarding sampling methodology, as well as those on whom the impact of such a system would be most serious. The feasibility of arriving at exposure data

for the total population by (3) *a sampling of practitioners of the healing arts* was also examined and will be reported separately as task rc.

The different methods which might be applied to direct sampling of the population or sampling of medical institutions which were reviewed in preparing this report are:

1. Mail questionnaire sampling;
2. Personal interview sampling;
3. Dosimetric instrument survey sampling.

Basic to a consideration of the problem is the assumption, which can be adequately substantiated, that analysis of data derived from an adequately designed sample, making appropriate allowances for all of the variables involved, can provide information applicable to the entire group under consideration. A further consideration is that by the use of sampling techniques it is possible to limit the number of individuals studied and the amount of data collected to a degree where a greater effort can be expended on each individual or group, and thus the accuracy of the resulting data and its analysis may be higher. It can thus be assumed that if a sampling procedure is used, the accuracy of the final data may exceed that obtained from a survey of the total group.

Various methods are available for collecting the data from the sample population but there are certain elements common to them all. Although the object of the survey would be to obtain data regarding the total radiation exposure of the sample population, this population would not be in a position to provide quantitative information regarding its exposure. Therefore, the most optimistic estimate as to the information that could be obtained directly from the sample indicates that no information beyond the presence or absence of exposure during a recent relatively short time interval would be forthcoming, together with information of indeterminate accuracy regarding the source of exposure. Thus, a study of a sample population would not, by itself be expected to provide the desired information. The extent to which even limited information might be obtained cannot be determined without the use of a pilot study or presurvey. Experience accumulated to date on the basis of other sampling does not provide firm figures on such important elements as cost and accuracy, because of the peculiar circumstances attending the problem of radiation exposures.

Regardless of the approach to the problem it can be said with definiteness that the information obtained by any sampling technique, would not be of appreciable value pending a report from task 1 indicating substantial accomplishment of its objectives. The possible use of an instrument sampling procedure as a substitute for information from task 1 will be discussed later in this report.

EFFECTS OF ATOMIC RADIATION

The three possible methods by which information might be obtained in a sample population and which have been considered are: (1) mail survey; (2) a survey by personal contact; and (3) survey by instrumentation.

Mail questionnaire

A survey by this technique would involve the preparation of a questionnaire, properly designed to elicit the desired information from all individuals in the sample, which by definition would require that it be understandable to persons at all socioecenomic levels. This is, of course, an impossible task, and the question is actually one of the degree of inaccuracy which would result. The experience of radiologists whose practice includes a broad spectrum of patient types indicates that a very significant segment of the population does not have accurate knowledge concerning the presence or absence of X-ray exposure as differentiated from other therapeutic or diagnostic procedures such as diathermy, infrared, etc.

Additionally, there is a large element of error concerning many individuals' knowledge concerning the correct name and address of the source of the exposures. The response of a general population sample to mail questionnaires is notoriously poor, and is subject to an extremely large element of bias. These considerations have been sufficiently serious and have led to such serious error in the data obtained that it can be assumed that a mail survey would not yield data adequate to accomplish the objectives.

Sampling by personal contact

The overriding difficulties and complications of a mail sampling technique for the population have been so serious that, in spite of the relative economy, this

technique has been largely supplanted by surveys by trained interviewers, making personal contacts. This latter technique has been developed to a relatively high state of perfection and is widely utilized in this country for many purposes. The accuracy to which data in general can be provided by this technique has also been established.

In examining the various existing systems which might be put to use to meet the problem at hand, the two which appeared most appropriate were the national health survey of the United States Public Healh Service and the current population survey of the Bureau of Census. These two systems were therefore examined in more detail.

The national health survey of the Public Health Service is currently in a state of development. It is proposed as a continuing survey of a sample population for the purpose of providing a wide variety of information regarding health status. It represents one method by which the information currently available to the population concerning its radiation exposure might be assembled. At present, however, the national health survey is still in relatively early stages of its operation, and there would likely be an appreciable time delay before it would be desirable to introduce questions regarding radiation exposure to supplement the current questionnaire.

The current population survey of the Bureau of the Census is a continuing survey which has been in existence for some time. It surveys a population sample consisting of approximat ly 35,000 households. The nature of its operations is such that it would appear feasible to introduce a small number of questions regarding radiation exposure and obtain a compilation of the resulting data in the period of a few months. The cost of collecting such data from a sample population has been estimated at $10,000 to $50,000 depending upon the number and nature of the questions to be asked. The sample survey is a fair representation of the entire United States population except that it excludes the resident instiuional populaion. The exact exent to which his exclusion would affect the validity of the resulting data is not immediately apparent. In terms of the total United States population, however, this group is relatively small. Although the total radiation exposure of this group may not be insignificant, yet it is likely that the reduced reproductive probability of this group, together with its small size, would not introduce a major source of error in determination of the total dose to the genetically significant population.

It is important to recognize, however, the limited amount of information which could be obtained by this means. As pointed out above, it must be assumed that the population does not have accurate data concerning radiation exposure in terms of roentgens. The most that could be hoped for would be some indication as to the number of individuals exposed to radiation in any given period of time, with some data regarding the source of exposure. In order to convert this into meaningful terms, it would be necessary to contact the source of exposure with the hope of obtaining dose data. It is not reasonable to attempt to assess the probable cost of converting the original information received from the survey into usable form, nor the accuracy of the final data, at this time. The cost and effort of obtaining the information which the current population survey might provide appears so reasonable, however, that serious consideration should be given to utilization of this approach with the expectation that, even if the information were not adequate to accomplish the desired results, it would be worthwhile from the standpoint of future planning.

Survey by instrumentation

The possibility was also examined of arriving at a figure concerning total population radiation exposure by means of a survey of a sample of the population to whom appropriate individual radiation dosimetric instruments are provided. This method would require the individual to use the instrument each time he received a radiation exposure. The obvious advantage to a survey of this nature is that it would not require successful completion of task 1 before it might yield data. It would, however, presumably require a personal visitation to all members of the sample population, with adequate instruction on how to use a properly designed meter for recording the exposuure at any particular time. If the current population survey of the Bureau of the Census can be taken as a proper indication, a fair population sample might involve something in the order of at least 35,000 househol ds on a preliminary basis. It is entirely possible that, in view of the fact that the current incidence of radiation exposures for the population is somewhat indeterminate at least in its distribution,

the results in this population group will not provide a sufficient number of positive replies to be statistically adequate.

For this reason it cannot be concluded that 35,000 households would necessarily represent an adequate sample for this purpose. It does give some appreciation of the minimum sample size, however. On this basis it is assumed that the number of instruments to be distributed, used, processed, and recorded, would be at least 100,000. The total cost of such a survey would, then, approximate at least several hundred thousand dollars. Again, there is no satisfactory experience on which to base an estimate as to the accuracy of the data which would be obtained. An obvious source of error would be in failure of individuals in the sample to use their instrumentation correctly, if at all, during a radiation exposure. It seems fair to assume that this would introduce a very large source of error and that there would be an appreciable bias in this error, as the failure to utilize the instruments correctly would be a function of socioeconomic status and other factors which might be related to total radiation exposure. Many other factors would have an important bearing on the results of such a study, not the least of which would be the psychological impact upon the persons surveyed, as well as the impact on the practitioners of the healing arts. In many cases, valid objection on the part of the practitioners could be expected with reference to confidentiality of medical information and related problems. This sampling problem is so unique that even approximate answers to the problems involved and probable accuracy of data could not be given until it has been tried on a pilot basis. The limited nature of this feasibility study does not permit a conclusion as to whether or not they are insurmountable.

INSTITUTION SAMPLING

Approaching the problem of total population radiation exposure by a sampling of medical institutions would appear to be appreciably less difficult than would sampling the population. At the same time, however, the information obtained would be incomplete in several important respects:

1. Although medical institutions presumably represent a major source of radiation exposure of the population, the extent to which noninstitutional practice contributes is one of the major unanswered questions and would not be resolved by this type of study.
2. The information already available concerning institutional practice is appreciably more adequate and accurate than similar information regarding noninstitutional practice, and it might therefore be argued that this area is in least need of emphasis.
3. Since institutional practice can by no means be considered average for the practitioners of the healing arts as a whole, there is a strong element of bias if these figures are extrapolated to the general population.

Among the advantages of such a study would be the relative ease and relatively low cost involved. A vast majority of the medical institutions in this country which would be likely engaged in a large scale use of radiation are affiliated with the American Hospital Association. Thus, there is an existing facility to assist in implementation of such a study. The impact on the medical institutions of compiling and reporting on the data requested would be appreciable, however. Only a few highly selective institutions would have the required data readily available. Thus the task to the large majority of institutions would be quite formidable. This would obviously affect the cost to the reporting entities and would introduce a major element of bias.

The American Hospital Association is currently conducting, at the request of its Committee on the Use of Radioisotopes in Hospitals, a survey on the use of radionuclides. The experience of this survey should provide some data concerning the cost and probable accuracy of a study in the radiation field. It is estimated that this survey will cost between $1,000 and $10,000. Based on previous experience with surveys by the AHA, the yield may well be 50 to 75 percent. There are several reasons why these figures should not be translated directly for use in a general radiation exposure survey, however. For example, the isotope survey is being conducted on a total study, rather than on a sampling basis. A very large percentage of replies is expected to show no use of radioisotopes and therefore will not require a major effort on the part of the reporting institution nor will they contribute appreciably to the problem in the compilation of data.

If it were decided to approach the problem of exposure in medical institutions by personal contact rather than by mail questionnaire, one of the major

factors which would increase the cost would be the necessity for adequate geographic distribution. It is assumed that there is a highly significant element of "clustering" which tends to result in significant variation among institutions when all factors except geographic location are held constant.

A survey of medical institutions using the instrument sampling technique would appear to have similar characteristics to a survey by mail questionnaire or personal contact. The important difference with regard to feasibility is that sampling by the instrument method would not require the successful completion of a major portion of task 1 as a prerequisite. In fact, such a survey might be expected to yield important information helpful in the completion of task 1. A byproduct of an instrument sampling project which might increase its value would be the inevitable educational impact which would result.

SUMMARY

The possible utilization of sampling techniques applied to the entire population and to medical institutions as a means of deriving data regarding the total population radiation exposure has been explored. Definitive answers regarding the feasibility of such projects cannot be provided until pilot studies have been made. In general, a sampling procedure should provide information with equal or greater accuracy at appreciably less cost than would a total population study. Sampling of the population by mail questionnaire would probably not yield sufficient data to be justified. Sampling of the population by use of an existing system, such as the Bureau of Census current population survey might be expected to provide some data regarding the presence or absence of radiation exposure history over a relatively short period of time and would probably provide much information regarding the feasibility of more extensive population studies. Sampling of the population by instrumentation would probably not yield information of sufficient accuracy to be warranted.

Sampling of medical institutions would probably yield additional data regarding radiation exposures at such institutions. This information would not be susceptible to extrapolation to noninstitutional radiation exposure unless it could be proven to be typical of the latter, a situation which is highly improbable. Sampling of medical institutions by personal contact or instrument sampling would obviate the need for prior completion of task 1 and might provide significant information of value in completing that task. If task 1 were successfully completed, however, the information to be derived by personal contact or instrument sampling of medical institutions might not be significantly greater or more accurate than could be obtained by mail questionnaire and would be appreciably more expensive and difficult.

[Task 4a and 4b, United States]

FEBRUARY 28, 1957.

APPROXIMATE METHODS FOR MEDICAL X-RAY EXPOSURE DETERMINATION

The determination of the average gonadal dose received by the public due to medical procedures by approximate methods requires information on certain specific points. It is assumed that some of the information mentioned in task 1 is available; i. e. that for every type of examination or treatment a gonadal dose can be assigned. Survey of the scattered measurements reported in the literature determines these only approximately.

The objectives of approximate methods consist primarily of the establishment of the following additional items:

(1) Number of different specialists in the various categories which use X-rays medically. These categories include: (*a*) hospitals; (*b*) clinics; (*c*) radiologists in private practice; (*d*) general practitioners; (*e*) physician specialists;[1] (*f*) osteopaths; (*g*) chiropractors; (*h*) chiropodists; and (*i*) dentists.

(2) The number of patients examined or treated annually in each of the above categories classified according to age and sex.

(3) Distribution of the type of examination or treatment by each of these patients in (2) in each of the categories in (1).

---

[1] Physician specialists include: Pediatrics orthopedic surgery, general surgery, internal medicine, industrial medicine, urology, gastroenterology and tuberculosis, obstetrics and gynecology, eye, ear, nose, and throat, cardiology, dermatology, allergy.

The establishment of these three points together with information on the gonad dose per examination, and such statistics as total population, age distribution of population at birth of each child, etc. then permits a determination of the genetically effective gonad dose per examination.

The data on (1) are available partially from Public Health Service records and reports by Modern Medicine Survey, the 1951 report by Dr. Donaldson, American Medical Association, and American Dental Association. The number of practitioners in the categories (1*a*, 1*b*, 1*c*, 1*d*, 1*e*, and 1*i*) and the number of X-ray units which they employ are believed known within about ±10 percent. The accuracy of the numbers of osteopaths, chiropodists, and chiropractors who own X-ray equipment is much less certain.

(2) With regard to the number of patients examined in each of the categories, information is available for some hospitals (1*a*) and clinics (1*b*). Much of this information is not available in a convenient form because of the way in which the records in many hospitals are kept. In some instances analysis is greatly facilitated by the records of group health plans such as the plan used in Little Rock, Ark. Another plan worthy of note is the Commission on Professional and Hospital Activities in Ann Arbor, Mich. Their record form provides complete information on all of their patients and specifically includes total information with regard to X-ray studies. There are group health plans in various parts of the country which also have sufficiently good records to supply data on the number and type of X-ray treatments taken by their patient members. A similar study, of a more specialized nature is the compilation of obstetrical data including number and type of X-ray examinations from a number of hospitals which is under the supervision of Prof. Schuyler Kohl at the College of Medicine of the State University of New York in New York City (Kings County Hospital). However, the vast majority of the hospitals in this country do not have their records in such a conveniently available form. Wtih regard to the general practitioners (1*d*), information is available from surveys made by the National Electrical Manufacturers Association (NEMA). Based on questionnaires, they have estimated the number of general practitioners who own X-ray equipment, what kind of equipment, and the number of radiographs and fluoroscopies performed weekly by the practitioners. Unfortunately such information does not exist for the other categories (1*e*, 1*f*, 1*g*, and 1*h*) listed above.

With regard to the third point above, distribution of type of examination or treatment in each of the categories is available from individual hospitals and clinics and some individual radiologists and general practitioners. With much effort this information could probably be obtained from most of the hospitals and radiologists. However, this information does not exist for the other categories listed above (1*d*, 1*e*, 1*f*, 1*g*, and 1*h*).

It can be concluded on the basis of the reports and sources referred to above, that for certain small collections of patients accurate information on points (1), (2), and (3), is obtainable. This represents a small sample of the total patient volume so that there is an unknown, and possibly large uncertainty in the reality of estimates in these bases.

DATA BASED ON FILM SALES

Information with regard to the total number of radiographic examinations made annually can be obtained from data supplied by film companies. Allowing for uncertainties in the knowledge of the company of the final destination of their film, it is estimated that the total number of radiographs can be determined to within 20 percent from the use of film data from manufacturers. The distribution of this film with regard to size, but not sensitivity, is also partially available. Further contacts with film companies may well produce more information. The records of the Department of Commerce provide information on the importation of film, and also on the amount of film exported annually with some idea of its destination.

For the first three categories above (1*a*, 1*b*, 1*c*) it is possible to give an estimated classification of radiographic examinations and relative frequency based on only limited supporting data. Presently available data do not give directly the distribution of examinations by types. The relative number of examinations in the indicated age groups is estimated as: 0–15 years, 15 percent; 16–30 years, 20 percent; 31–50 years, 35 percent; and above 50 years, 30 percent. As an overall average, three films are used per radiographic examination.

DATA OBTAINED FROM X-RAY TUBE RECORDS

Through the National Electrical Manufacturing Association some data are available with respect to tubes produced and sold in the United States annually. These data apply to about 80 percent of the tubes sold since the North American Phillips Co., Eureka Co., and Dunlee, Co. do not participate in the NEMA. These data on X-ray tubes are not sufficiently complete to provide information on those indtended for a specific radiographic installation or whether or not they are to be used primarily for fluoroscopic or radiographic purposes. NEMA has no records of dental tubes. The census of manufactures (Department of Commerce) has data on annual tube production but these do not distinguish between medical and industrial use.

The records of the Department of Commerce include the importation and exportation of X-ray tubes but do not indicate whether they are therapeutic, diagnostic, or other.

There is no automatic way of determining the mean value of the quantity of electricity which passes through the diagnostic tube during its life, nor are the available lifetime records of individual companies very good on this point. Rough estimates can be made by individuals experienced in the X-ray field.

[Task 4c, ICRP/ICRU]

APPROXIMATE METHODS: QUESTIONNAIRE TO PROFESSIONAL PEOPLE

FEASIBILITY STUDY FOR THE UNITED NATIONS SCIENTIFIC COMMITTEE ON THE EFFECTS OF ATOMIC RADIATION

The feasibility of obtaining data on the total population radiation exposure by means of a mail questionnaire to professional people was explored. Before presentation of the information obtained, the following two points should be made clear: (1) the medical profession in most instances lacks the exposure information needed to answer the questionnaire. Information would be needed regarding the radiation exposure under all of the varying conditions present in each individual examination. In other words, such a questionnaire would be essentially unsuccessful in terms of actual dosage until completion of task 1, (2) experience with all of the variables involved in questionnaires to professional people indicates that definitive answers as to the feasibility, sample size, cost, and related questions cannot be given until the particular survey in mind has been tried on a sample or presurvey basis.

It is apparent that a correctly designed sample could provide information regarding radiation exposure with an accuracy which would equal or exceed that of a survey of all professional people.

Among the major factors which might affect the feasibility of a survey of this nature are the cost, sample size, percentage return, and probable accuracy. Unfortunately, none of the surveys done to date among professional groups are completely comparable to the ones suggested here. Certain principles and technical factors can be extrapolated, however. Thus, in considering such a survey, it would appear desirable to select the sample to be queried by stratifying professional people into groups depending upon the probability of their making a significant contribution to the total radiation exposure of the population. The proportion of the total number within each stratum which it would be necessary to sample depends upon the contribution of that stratum to the total radiation exposure as well as other factors.

Thus, it might be desirable and feasible to query all of those practitioners in the group likely to produce heavy radiation exposure, such as radiologists. Among certain medical specialties where the use of radiation might be quite heavy (but presumably not as great as among radiologists) one would sample only a percentage, for example, one-quarter of those involved. Among those individuals with an expected moderate and light use of radiation, an even smaller percentage could be sampled, for example, 1 in 20. Additionally, there would be a group which could be segregated on the basis of type of practice (such as administrators, public-health workers, or psychiatrists), where it could

be assumed that there is no use of radiation or that the use is so slight as to not affect the total radiation dose of the population.

Basing estimates on this approach to the problem it is possible that a reasonably accurate estimate might be obtained by a survey of something in the order of 10 percent of the total professional group. Based on an estimate of approximately 250,000 physicians in the country, would lead to a sample size in the order of 25,000. Whether or not this sample size would be adequate could not be finally determined until after returns were received, although it could be estimated on the basis of a pilot study. One of the major factors in determining the adequacy of the sample would be the percentage of satisfactory returns. The difficulty of estimating the percentage returns is indicated by the fact that although many surveys have considered a return of 10 to 25 percent to be quite satisfactory, one survey currently being conducted has shown a return of over 90 percent from a mail questionnaire with 2 or 3 mail followups. Much of this variability in the percentage return can be accounted for by the interest of the profession and the stimulation and support given by prominent governmental and nongovernmental agencies, as well as the difficulty of answering the questionnaire.

Experience indicates that if mailing lists were available and did not have to be compiled separately, a mail questionnaire with 2 or 3 mail follow-ups costs in the order of $2.00 to $5.00 per questionnaire, not including the cost of the analysis of the returns. Thus, a preliminary estimate can be made that the cost of the questionnaire procedure, not including compilation of the data and analysis of the returns would be within one order of magnitude of $100,000. The cost of analysis of the data is even more difficult to estimate. It would appear almost certain to exceed the cost of the questionnaire itself, but the factor by which it exceeded the cost of the questionnaire would be determined by the nature of the replies and the extent to which it was desired to extract detailed information.

The impact on the persons queried could range from minimal to essentially impossibly serious depending upon the amount of information requested. One of the more important problems in this connection would be the time period over which exposure data were requested. It seems reasonable to assume that providing a relatively small amount of information covering operations for one day or possibly for one week would not represent an unjustified imposition on the reporting entities. On the other hand, data would, in most cases, not be readily available for any extended period of time and it would therefore be necessary for the data to be compiled especially for the purpose of answering the questionnaire. Therefore, if data were requested for a more extended period of time, for example, a month or a year, the problem to the reporting entities of compiling these data would become so great that, if replies were received they would probably be grossly inaccurate.

The question as to whether or not sampling for a short time interval would be adequate is difficult to assess. There certainly would be some errors brought about by seasonal or weekly variations but the errors thus introduced might not be sufficiently great to adversely affect the final data. This is a point which could be resolved only by repeated sampling for short periods of time on several occasions, thus spreading the task of completion of questionnaire through different groups, or by sampling within the sample for possible time variations. If the latter method were used it might be necessary to provide financial or other support to this sample of the sample in completing its task.

In summary therefore it can be stated that:

1. A sampling among physicians would not provide the desired data regarding the total population exposure until substantial progress is made toward the completion of task 1.

2. The firm estimates of even such fundamental items as sample size and overall costs cannot be made until a pilot study has been conducted.

3. It appears likely that, if sufficient information were available from task 1, a sampling of the medical professions by mail questionnaire, with the use of proper controls could provide valuable information regarding total exposure of the population to radiation.

4. Pending the conduct of pilot studies it seems reasonable to assume that a mail survey of a sample of the professions would be a large, but feasible task, following completion of task 1.

[Task 5, United States]

GONADAL RADIATION IN THE GENETICALLY SIGNIFICANT PORTION OF THE POPULATION DERIVED FROM RADIOACTIVE ISOTOPE PROCEDURES IN MEDICINE

GENERAL CONSIDERATIONS

In analyzing the contribution of gonadal radiation derived from radioactive isotopes in medical practice, the first consideration is to deal only with patients in the genetically significant portion of the population. For this purpose we will use only the age group from conception to the age of thirty. The second feature is that within this patient group, the only significant radiation is that which is given to the gonads before children are conceived by these patients, and this immediately discards a considerable number of very ill patients who have no chance of conceiving children after therapeutic procedures, those in whom sterility is a necessary antecedent or result of therapeutic procedures (as in carcinoma of the cervix and carcinoma of the breast), as well as some more subtle features which have to do with conception being less likely in people who have had serious medical problems. In setting up a valid statistical study, all of these features would have to be included as well as a proper study of the numbers of procedures within the specific separate ages involved. We do not have anything which approaches satisfactory data on these aspects, but in the discussions below, some attempt is made to bring them into focus. At any rate, it is unrealistic to take the total shipments of curies of any particular isotope from Oak Ridge and to assume a high proportion of utilization within the genetically significant population, because by far the larger doses are used in the treatment problems which automatically limit the probability of conception in the large dose treatment cases.

The problems of dosage delivered to the gonads in any particular case of the use of a specific isotope for a specific purpose are not easy. The beta and gamma components must be individually considered and with due regard to the geometry of the position of the ovaries or testis, not only in relationship to the whole body general distribution of a specific isotope, but also for such special features as radioiodine concentration in the thyroid, urinary bladder, stomach, etc. in certain phases of the metabolic management of the isotope, with special respect to the gamma component. The beta component must take due regard for minor degrees of specific localization in the gonads which would not be accurately available without biopsy and assay, but which can be accurately available without biopsy and assay, but which can be estimated from "blood dose" or from actual assays at necropsy or in surgical specimens (see reference by George S. Kurland and A. Stone Freedberg).

MOST USUAL TYPES OF ISOTYPES EMPLOYED IN MEDICAL PRACTICE. (INTERNAL USE ONLY).

The following is a listing of the most common current uses of radioactive isotypes with notations as to the type of patients for each use and some comments as to the age grouping, life expectancy and probability of conception of

children within these groups. The relationship of the procedures to gonadal radiation when significant are analyzed separately below:

Isotope	Type of use	Type of patients (with respect to age and life expectancy)	Relationship of dose of gonadal radiation in significant population
I^{131}	A. Diagnostic: Thyroid tracer scans, etc.	Used in all ages, but cautious choice in children.	See analysis below (I).
	B. Treatment: Hyperthyroidism	Most users conservative about use below age 30; require special indications.	See analysis (II).
	Cardian and pulmonary disease.	None below age 30	No significant contribution.
	Thyroid cancer	Few cases below age 30. Only used in cases with metastasis. Life expectancy short. Children after treatment relatively unlikely.	Do.
	C. Combined diagnostic; RISA, tagged dyes, etc.	Some studies done below age 30; small tracer doses, short, effective half-life.	See analysis (III).
P^{32}	Treatment: Polycythemia vera	Very rare below age 30	No significant contribution.
	Breast cancer (advanced)	Very few below age 30 and all sterilized before P^{32} given.	Do.
	Leukemia	Few cases below 30 and chances of having children almost nil after P^{32}.	Do.
	Colloid in advanced cancer or leukemia.	do	Do.
Au^{198}	Serious effusions (malignant)	No cases likely below age 30. Very limited life expectancy.	Do.
	Leukemia		Do.
	Carcinoma of cervix	Very few cases below age 30. Children nil after treatment.	Do.
	Carcinoma of prostate	Very few cases below 30. Chances of having children very remote after treatment.	Do.
	Diagnostic: Liver scans for malignancy, etc.	Almost no cases below age 30; very limited life expectancy.	Do.
Cr^{51}, Fe^{59}	Red cell volume, life, etc.	Some studies below age 30. Small doses. Good proportion of patients quite ill with limited life expectancy.	See analysis (III).
Na^{24}, K^{42}	Metabolic states	Few studies below 30. Most patients quite ill with limited life expectancy.	Do.
Co^{60}	Labeled Vit. B_{12}	Few cases below age 30 for differentiation of pernicious anemia and nontropical sprue.	Do.

ANALYIS OF SITUATIONS IN WHICH GONADAL RADIATION DOSE SEEMS POSSIBLY SIGNIFICANT

I. Diagnostic studies of the thyroid by tracers, scientillation scanning, etc., with radioiodine I^{131}

In the papers by Trunnell et al., and Kurland and Freedberg, the beta components of dosage per millicurie of I–131 are listed as follows: ovary 0.6 rads per millicurie; testis 0.3 rads per millicurie. In the paper by Seidlin, et al., the beta and gamma components together are approximately 0.6 rads plus or minus 0.3 per millicurie. To this might be added approximately 0.1 to 0.3 rads per millicurie from the transient dosage in the bladder in the case of both ovary and testis.

Using a 25 microcurie tracer, the average dose to either ovary or testis might be estimated at approximately 0.015 rads per tracer procedure. A rough analysis of the number of tracer studies performed in the United States per year would suggest that approximately 150,000 to 200,000 would seem like a reasonable figure. Of these, probably not more than 25,000 are performed per year in patients below the age of 30 and in the genetically significant group. On the basis of these figures it turns out that only approximately 375 rads would be delivered by all of the tracers in the genetically significant portion of the population from this tracer used. Even if the frequency of such studies is considerably greater than listed, it still would not get into a figure which is of any great concern.

II. Treatment of hyperthyroidism with radioactive iodine

Using the same source material as listed above, a 10 millicurie (rather large) full treatment dose of radioactive iodine would give approximately 6 rads to the gonads. On the basis of approximately 2 million persons, it seems unlikely that over 1,000 or at the most, 2,000 hyperthyroids below the age of 30 and in the genetically significant group are treated per year in the total population (the best estimate we can get for Philadelphia is about 15 to 30 such cases per year). Of course, Philadelphia might not be representative, but if it is more conservative with respect to the choice of patients, it also is probably somewhat better covered with respect to isotope users than one would expect for the average of the country. At any rate, the figures on this basis would be 6,000 to 12,000 rads per year to the total population.

III. Other tracer procedures such as blood volumes, red cell volumes, red cell life, tag dyes, etc.

The practice in different parts of the country in the use of these procedures, particularly in our selected genetically significant population is quite variable. At any rate, one would not think it reasonable that this would approach the more widespread use of radioiodine in thyroid studies, volumewise, and the dosage to the gonads derived in these studies is not usually as great as one would expect with the usual methods of radioiodine studies for the thyroid. If this reasoning is correct, one could assume that the maximum would not exceed the figure of approximately 375 rads as listed in example roman numeral one above.

SUMMARY AND CONCLUSIONS

The exact data for deriving the gonadal radiation contributed by internal radioisotope procedures in the United States within the genetically significant portion of the population is not available. In searching for a reasonable figure, it is not permissible to use the total distribution of radioisotopes from Oak Ridge because of the very great variations in the types of procedures, dosages, etc., that are used for different conditions and because of the very different practice within age groups and life expectancy groups within the population. A great majority of treatment procedures are used in patients who cannot have any reasonable likelihood of adding to future populations. In the whole spectrum of internal radioisotope use, only three major procedures seem to contribute significantly to the gonadal radiation that we are interested in. Thyroid tracer studies probably do not account for more than 375 rads per year to the entire population (this probably should be expressed as 375 man-rads per year). All other tracer procedures within this population group would not seem to add more than an equivalent additional 375 man-rads. The only probable contribution treatmentwise is in the treatment of hyperthyroidism with I–131. This most likely does not contribute over approximately 6,000 to 12,000 man-rads per year.

ADDITIONAL COMMENT

In trying to compare the figures so derived with those of Stanley Clark, one should divide the totals, something less than 15,000 rads, by 60 million persons as representing the population below age 30 and this gives a figure of 0.00025 man-rads per potentially genetically significant person per year in the United States. Clark's figures for radioiodine represented a very small portion of his total "theorizing", but were some 32 times larger (0.008 roentgen per year per person). He ignored the selection of the age and procreative potentiality, except as an afterthought in his summary and discussion and thought that it was compensated for by underestimates in other directions. He furthermore thought that his estimates would not likely be off by any such large factor. It is my considered opinion that Clark's approach to this problem is entirely unwarranted and has led him to ridiculous conclusions. It is Clark's paper which is the only one that Doctor Laughlin quotes from in his comprehensive summary of the literature on the subject.

OTHER ITEMS

The question has been raised as to the distinction between exposures of individuals and of population groups. This has been considered for many years. Where exposures run to fairly high levels it is desirable that exposure records be kept for individuals. Where exposure levels are low and where the persons exposed may be random segments of the population, it is not important to retain this information by individuals. For low doses, of the order of perhaps 50 roentgens average, per individual, per lifetime, the effects are probably so marginal that averages of population suffice for all analytical and record purposes. For genetic damage it is the total dose to the whole inbreeding part of the population that counts most. There may be some exceptions to this for large individual doses. In summing up the genetic damage it is important to weed out that part of the population in which there is expectation of having children.

For somatic damage the individual is the controlling unit but on the assumption that there is no threshold exposure and for low exposure levels the dose averaged over the whole population is the primary factor influencing the statistical risk to an individual.

A question has been raised as to the possible effect of the use of different protection standards by states or nations. This is somewhat of an academic question because such a situation does not exist. In the United States the basic protection standards, as set by the NCRP, have been adopted without exception by the individual States and by the Federal departments concerned. Over the world all nations, including the Iron Curtain countries, presently use the standards set by the ICRP. As noted above these are the same as those established by the NCRP. (For further information on international recommendations see Recommendations of the International Commission on Radiological Protection published as supplement No. 6 of the British Journal of Radiology, London, 1955.) This report is presently under some revision. Because of the national and international acceptance of existing standards it is not deemed likely that confusion will result from the use of different standards.

A problem does exist, however, on both a national and international basis, namely, that there seems to be developing a plethora of organizations that want to set up various kinds of radiation protection bodies or committees.

(Exhibit 23 is as follows:)

JANUARY 19, 1957.

EXHIBIT 23: RELATIONSHIP BETWEEN VARIOUS TECHNICAL BODIES AND THE INTERNATIONAL ATOMIC ENERGY AGENCY

In paragraph 6 of article III–A, describing the functions of the new International Atomic Energy Agency, the following statement is included.

The Agency is authorized "to establish or adopt, in consultation and, where appropriate, in collaboration with the competent organs of the United Nations and with the specialized agencies concerned, standards of safety for protection of health and minimization of danger to life and property (including such standards for labor conditions), and to provide for the application of these standards to its own operations as well as to the operations making use of materials * * * made available by the Agency * * *."

This is a rather all-inclusive statement but one of the given parts undoubtedly refers to matters of protection against the harmful effect of radiation. It is particularly in this area that clarification as to area of responsibility is needed.

It is essential that as far as possible the IAEA make use of existing organizations and facilities in this field, rather than to establish a new radiation protection organization of its own. One reason for this is the fact that there is a critical shortage of individuals in the world who have broad experience in the radiation protection field. This small number, which probably does not exceed some 2 dozen internationally recognized experts, is already called upon repeatedly by different organizations to perform the same or very similar functions, but usually under different organizational units. This is not only wasteful of manpower but it is already overstraining this small group of experts. At the same time such a multiplicity of committee activities may lead to areas of conflict, and certainly leads to uncertainty as to which recommendations carry weight. To illustrate the problem, there are listed below some of the organizations and activities already well established in the field.

The International Commission on Radiological Protection (ICRP) was established in 1928 and since that time has provided the international philosophy and guidance in the broad field of radiation protection. Their recommendations have been followed throughout the world. The International Commission on Radiological Units and Measurements (ICRU) was established in 1925 and its recommendations are also used almost universally. The ICRP and the ICRU are sister commissions, originally sponsored and still operating under the aegis of the International Congresses of Radiology. The commissions usually held their meetings jointly.

The ICRP and the ICRU entered into official relationship with the World Health Organization (WHO) in February 1956, as a nongovernmental participating organization. In this capacity the two commissions are regarded as the scientific bodies for developing the standards of radiation protection and units for WHO. WHO, in turn, will undertake the publication and dissimination of this information throughout the world.

As a result of an offer by UNESCO, an informal relationship exists between the ICRU and UNESCO, in that the latter has provided some financial support to assist in the establishment of radiation standards in various countries. The mechanics of this will be handled through WHO.

In 1956 the United Nations established its Scientific Committee on the Effects of Atomic Radiation. Included in the membership is a substantial number of individuals who are also members of the ICRP and the ICRU.

In September 1956, the U. N. Scientific Committee requested the ICRP and the ICRU jointly to undertake certain studies related to the evaluation of radiation exposure to man, and the U. N. has provided some financial assistance for this study. The program is now underway in about 15 countries and there is a substantial overlap of membership between the various participants in the study, the two international commissions and the U. N. Scientific Committee. At the moment it is not clear to what extent the U. N. Scientific Committee will use the joint commissions as the technical bodies that should be responsible for specific technical tasks, but there is some implication that some official relationship may develop.

The International Labor Organization (ILO) has a Consulting Committee on Radiation Protection. This includes individuals who are also members of the U. N. Scientific Committee, the ICRP and the ICRU. They are developing standards of protection in the industrial field including atomic energy installations. A meeting of this committee is planned for the fall of 1957 for the purpose of reaching agreement on the ILO radiation protection recommendations.

The International Standards Organization (ISO) is a recognized nongovernmental body having official relationships in many countries as, for example, the American Standards Association in the United States. The ISO has recently indicated that they plan to expand their scope of interest to include all phases of atomic industry including radiation protection and have applied to UNESCO for recognition as the standards body primarily responsible in this area.

In a recent communication from the Secretary General of the WHO, it is understood that he is establishing some kind of advisory committee on radiation matters. The relationship between this and the various other bodies mentioned above is unclear.

93299°—57—pt. 1——57

The brief outline above typifies the complicated world situation that is developing in the field of radiation-protection standards. Of all of the organizations mentioned above, the only ones that have been in continuous and active existence for any length of time are the ICRP and the ICRU. Every time a new organization is set up, many members are drawn from amongst the members of these two commissions. Fear is expressed that this same situation may develop in the event that the IAEA decides to organize a radiation protection group. It can only draw upon the same limited number of qualified people; there are no others. It would appear to be desirable for the IAEA to take advantage of existing organizations, rather than to establish new ones. The same ends would be accomplished, but they would be accomplished more rapidly without the time and effort involved in establishing a new organization and membership, and with a higher degree of enthusiasm because of the good working relationship already existing between the members of the existing groups. In this way also the IAEA will be dealing with an organization that has been preeminent in the field of radiation protection and units for many years.

POSITION PLAN

In view of the existence of well-established internationally recognized organizations having high competence in the broad field of standards of radiation protection and units, it is recommended that such organizations be utilized by the IAEA as the official technical body for the development of the necessary standards for use by the IAEA. Specific reference is made to the International Commission on Radiological Protection and the International Commission on Radiological Units and Measurement. Since matters of radiation protection and units are largely in the same area of health, it is recommended that problems in this area be referred through the existing channels to the ICRP and the ICRU. At the present time the channel of communication would be via the United Nations; through the World Health Organization, an official specialized agency of the U. N.; to the ICRP and ICRU, a nongovernmental organization having official recognition of the WHO. Once a relationship and program has been established between the IAEA on the one hand, and the ICRP on the other hand, direct technical contact should be permissible with information and reports concurrently being put through the normal channels of communication.

By utilizing the above procedure, the IAEA can take full advantage of established competence in the field of radiation protection and units without the necessity of establishing a new and separate body of its own.

(Mr. Taylor's statement—continued.)

Manpower knowledgeable in the field of radiation protection is very limited and the same people the world over are called upon repeatedly for similar and overlapping activities. This is extremely wasteful of manpower effort and it was a similar situation on a smaller scale in this country that was instrumental in the formation of the NCRP in 1929. To avoid this situation on an international basis the ICRP and ICRU, jointly, are establishing formal working relationships with various interested international organizations while having certain specialized interests; nevertheless by common consent look to the ICRP and ICRU for their basic guides on radiation protection standards. With the establishment of the new International Atomic Energy Agency, it is possible that they will also require assistance in this direction. It is hoped that they will, along with the other agencies, look to the international commissions for this guidance rather than setting up a new and undoubtedly overlapping body of their own.

Representative HOLIFIELD. Our next witness is Dr. H. L. Friedell, School of Medicine, Western Reserve University.

Dr. Friedell, we are happy to have you here this morning. You may proceed.

STATEMENT OF DR. H. L. FRIEDELL, SCHOOL OF MEDICINE, WESTERN RESERVE UNIVERSITY[1]

Dr. FRIEDELL. Thank you, sir.

Mr. Chairman, and members of the joint committee, and ladies and gentlemen, I have the unenviable task of trying to introduce an exceedingly difficult and complex subject. We have gathered information on the whole problem of radiation, and the biological effects of radiation, essentially within the past 20 years, and I think it takes a little while before this matures so we can undertstand it fully. Nevertheless, I think there is a place for orientation here for examining some of the basic concepts of what we do know about radiation, about trying to separate various kinds of effects one from the other, when radiation is administered to a biological system. I would like to briefly introduce this.

Time is limited, but I think the others will very readily fill in any hiatuses that exist. There are many none of us can fill in, I think. They will augment wherever necessary the things I talk about.

Representative HOLIFIELD. While we are trying to keep to the schedule, we are not going to cut any witness short. We may ask for documentation, and if you have something that you feel the committee should know, you may proceed to give it.

Dr. FRIEDELL. I think we will want to take a look at how radiation introduces the biological effect, and then we will try to separate some of the things that occur.

It is interesting that radiation we cannot see, hear, feel, or smell, will initiate very profound effects, the way it appears to do this is by this radiation interacting primarily with the atoms that comprise the biological molecules.

The way they interact with the atoms is, in essence, interaction with their electron shells. Most of the physical changes involve these electron orbits, but there are some others which do occur which are essentially insignificant in the broad overall picture.

Specifically, an ionizing particle or powerful photon, a piece of electromagnetic radiation, will come in and pull away an electron out of the atom. Once it has done this, it has now disturbed the atom, made it into an ion, and this ionized atom and the electron will form an ion pair—or it may move the electron into a different energy level. Then it is excited, and may then concern itself with various chemical and biochemical reactions.

---

[1] Professional background: University of Minnesota, M. D., 1936; University of Minnesota, Ph. D., 1939; National Cancer Institute Fellow; Chicago Tumor Institute, 1939–40; Memorial Hospital, New York, 1940–41; University of California, 1941–42; instructor in radiology, University of California, 1941–42; United States Army, lieutenant colonel, 1942–46; executive officer and Deputy Chief, Medical Division, Manhattan District. Present work: Professor of radiology, Western Reserve University; director, department of radiology, University Hospitals of Cleveland; director, Atomic Energy Medical Research project, Western Reserve University. Committee appointments: Veterans' Administration, Central Advisory Committee, Radioisotope Section, Reserve and Education Service; National Research Council, Subcommittee on Radiobiology; Atomic Energy Commission, Advisory Committee on Reactor Safeguards; National Bureau of Standards, Subcommittee on Permissible External Dose; State of Ohio, advisory committee on atomic energy. Member; American College of Radiology, American Medical Association, American Radium Society, Association for Advancement of Science, Association of University Radiologists, American Roentgen Ray Society, Radiological Society of North America, Society of Experimental Biology and Medicine, Radiation Research Society, Sigma Xi, Alpha Omega Alpha. (Submitted by witness.)

When this occurs it is obvious immediately that the molecule that is then so vital and important to the cell has been disrupted or disturbed and many things can happen to this molecule.

It is of interest to observe that a cell has roughly 10 to the 14th molecules, and a thousand roentgens, a dose which generally is lethal, will affect only about 10 to the seventh molecules. In other words, one ten-millionth of these are affected, and yet this single injury to an atom or molecule among these many will introduce violent and very serious biological effects. The physical effects are over generally in a very short period of time. Immediately thereafter the disrupted molecules become involved in various kinds of chemical and biochemical changes. And again these are over in a few microseconds. So that the process of the physical effects and the biochemical effects are finished within a very, very short period of time, and yet we observe the biological effect in hours, days, months, and possibly even years later. This is an important concept to retain and keep in mind.

Representative HOLIFIELD. This statement is based on experiments with animals?

Dr. FRIEDELL. These are based on experiments primarily in vitro; in other words, studying tissues or systems outside of complex animal, because it would be very difficult to observe it in an animal itself. From the point of view of the occurrence of biological effects, these are observed in animals—correct.

Representative HOLIFIELD. And is applicable to man?

Dr. FRIEDELL. And is applicable to man.

Representative VAN ZANDT. Dr. Friedell, at this point, do you have information concerning the animals that were exposed to radiation in the Mariannas in the 1954 tests?

Dr. FRIEDELL. I am aware of it. I am not entirely familiar with it.

Representative VAN ZANDT. In other words, the Mariannas tests are not involved in your presentation?

Dr. FRIEDELL. I would say what I am going to present would be involved in all biological effects of radiation. These are the basic things that occur at the beginning. They really are the initial things, and I want to proceed much further in developing this.

Once we get the injury at the chemical and biochemical level, obviously the first unit that may be injured is the cell, and all organisms are comprised of cells, as we know, and are complex organizations of cells. We, therefore, can perhaps begin, once we take a look at this matter, to look at the cells themselves and see what kind of biological effects occur here.

Before I go on to the cell, I would like to make this point: Undoubtedly many of you are familiar with the effects of protecting cells with various chemical and biochemical agents. The way this has been done, in effect, is to take a look at some of the biochemical changes that might occur in a system, and see if it would be possible to prevent them or counteract them. Specifically, we might think briefly of a system that can be affected easily and studied readily, and that is the disruption of the water molecules.

Water is an abundant material in biological systems—ordinary biological systems. This water molecule will undergo exactly the same changes that any vital complex molecule might undergo in the cell itself, because the ionization makes no distinction between these. As-

suming roughly the same conditions, it will ionize water just as well as it will ionize anything else. And if you ionize the water, tear it apart, you now produce radicals, so to speak, which will either reunite or will be modified in some other way.

If oxygen is present, which is another very important element, and present in the biological system, they may combine with oxygen to make very powerful oxidizing agents.

It is presumed at levels we talk about, up to several thousand roentgens, that this effect, which is considered an indirect effect (in other words, producing ionization and modifications of the atoms that may not be directly involved in the biological systems, such as water), in turn produces serious effects, because they become noxious radicals, so to speak. They become oxidants, highly powerful oxidizing agents, and may, in the presence of very vital atoms or molecules, alter them and, in turn, produce these serious biological effects.

Therefore, if you were going to attempt biochemical repair of this, or chemical repair of this, you would either prevent the oxidation from producing radicals, or you might introduce something that is an oxygen acceptor, a reducing agent so to speak, and therefore either spare the effect on the molecules or in some way interfere with this occurring.

One of the common compounds we know fairly well is cysteine, which has sulfhydral groups. We do not need to go into the chemistry and exact nature of these things, but they will accept oxygen, and if you introduce enough of these into the cell, these will, in effect, either combine with the noxious radicals to start with, or by the statistical process of dilution prevent some of the vital cell molecules from being affected.

So that this is one attack that has been made in altering or in preventing this biochemical change from occurring and, therefore, being seriously damaging to the cell.

I said earlier that oxygen needed to be present in order for a large number of these oxidizing radicals to be produced, and this is another way in which we can protect the cell. You can reduce the amount of oxygen. You can either limit the amount of oxygen physically by putting the organisms in oxygen-free atmosphere, or by making some physiological change so that the oxygen is low in vital areas of the cell. When you do this you also protect the organism.

So that our beginning knowledge about the biochemical effects are extremely important in giving us an understanding how biological effects will occur, and how we might modify them in the biological system.

Representative HOLIFIELD. Does that have any practical effect on radiation sickness?

Dr. FRIEDELL. Unfortunately, its practical effect is rather small, for this reason: These things must be done immediately before the radiation is delivered, or at the time the radiation is delivered. Unfortunately, if it is done after the radiation is delivered, this, of course, is no longer effective because all of these things we are talking about would have occurred already.

Representative HOLIFIELD. So this is an interesting scientific fact, but from the standpoint of protecting the people from radiation it is inapplicable?

Dr. FRIEDELL. Essentially and practically inapplicable, but it is important in understanding the mechanisms that occur.

I think it would be well to then begin to take a look at what happens in the cell itself, and the people after me are going to talk about this, and extend some of the basic concepts further. But I believe it would be useful to look at the cells and see what we know about them from a radiological point of view.

We have for a long time studied the various responses of cells to radiation, and have made up a little chart which tells us something about how sensitive these are to radiation, and how easily affected they are by radiation. It is important to understand this because, if you are going to understand what happens to the whole organism, you must obviously know how dependent the whole organism is on the economy of any single cell and how easily this is affected by radiation.

I would like to read this to you from the statement that will be introduced in the record. I will read a list of cells I have made up and listed as extremely sensitive, highly sensitive to moderately sensitive, and insensitive.

The basic cells of the hematopoietic system—lymphocytes, erythroblasts, myeloblasts—closely associated, are extremely sensitive to radiation, and small doses will injure these cells severely.

In the same category, I would include the germinal cells of ovary and the germinal cells of testis. As far as our purposes, I would consider these as highly sensitive, and very readily and quickly affected by radiation.

Mr. RAMEY. When you use the word "lymphocyte" what would be the common name for that?

Dr. FRIEDELLL. I would guess that you call these the germinal cells in lymphatic tissues, such as lymph nodes and other tissues that are related to lymph nodes. These also possibly have their origin in the hemotopoietic tissue as well. In other words, the blood-forming organs as well. Perhaps that is what you were referring to.

The next group, which is a little less sensitive—and I would consider these as moderately sensitive to possibly highly sensitive—would be the epithelium of intestinal crypts lining the insides of the intestines, and certain basal layers that originate in the epidermis.

These basal layers of the epidermis and the epithelium of the intestinal crypts, I would say, would be less sensitive, but nevertheless easily affected by radiation.

Now, there are a group of cells which seem to be unaffected except by extremely large doses. I would like to say that all cells can be affected by radiation; if you introduce enough energy, transfer enough energy to the vital systems of the cell, you can destroy them all. But some of the cells require very large doses. Generally the way we look at this is that cells that are highly active and rapidly dividing seem to be affected by radiation more easily than those that are slower growing and more highly differentiated in the sense they are more highly specialized.

These latter seem to be affected by radiation less. I would include in these things like muscles, bone cells proper, liver cells, brain cells, nerve cells, kidney cells. And ordinarily, when lethal doses of radiation are given to the organisms, we will find that these cells are essentially unaffected. You can find no important change in the cells proper.

Now, if you begin to accept this—and it is somewhat difficult to digest without studying it a little bit—you can then begin to understand what happens to organisms as a whole when the organism receives large doses of radiation.

First of all, we can see that certain tissues are going to be promptly injured, and these tissues are going to be the blood-forming cells, such as the leukocytes, and the gastrointestinal cells. Most of the others will be unaffected.

If the organism is vitally dependent on the cells, it will be fatally injured. If it is not vitally dependent upon these cells, there may be modifications, but the organisms proper may not be injured. Therefore, we can begin to understand how we can injure certain cells and yet not affect the organisms seriously.

For example, you can give a fair dose of radiation, which might kill the organisms, to the liver cells alone, and yet the organisms will not die. You can give this kind of radiation to the muscle cells, for example, and the organisms will not die. On the other hand, if you deliver this radiation to the hemotopoietic system, the blood-forming tissue, the organism will die because these blood-forming organs are very vital to the cell.

One of the important things involved is defense against infection. That is, the white cells of the blood-forming organs are very important against infection, and, therefore, reducing the cells would seriously affect the organism and various kinds of infections would rapidly take over.

Representative HOLIFIELD. There is an old saying that a chain is only as strong as its weakest link.

Dr. FRIEDELL. Correct.

Representative HOLIFIELD. When we are talking about the effects of radiation on the human body, and the life span, we must of necessity address our remarks principally to the weakest link in evaluation of the radiation.

Dr. FRIEDELL. Right.

Representative HOLIFIELD. It is of small comfort to know that one section of the body is not so badly affected by radiation, if in the meantime another section of the body which is vital to existence has been destroyed.

I am not saying we should not know this, but I am saying the important thing is to evaluate its effect upon that weakest link in the life cell, the reproductive chain.

Dr. FRIEDELL. This is very true, and when we speak of total body radiation, in other words, when we irradiate the whole organism, then obviously we have to examine the weakest link, and the weakest link would be the hemotopoietic system, and the gastrointestinal tract.

However, when you deal with radio elements, they have certain preferential deposition, so to speak, and therefore, in order to orient yourself, you must understand that certain radio elements that may be administered to an individual will deposit themselves preferentially in one area and, therefore, will essentially have no effect on the gross economy of the individual.

One of the examples I can cite to you is the use of modest doses of radioiodine.

In the adult, the thyroid is a relative insensitive organ, and you can deliver doses to the thyroid in the order of 500 roentgens which

will to all intents and purposes produce no demonstrable effect. On the other hand if you gave 500 roentgens to the total body, or to a very vital structure, you would injury the animal perhaps fatally. This is the reason I introduce this.

Representative HOLIFIELD. By the same token, radio isotopes such as strontium 90, which have been deposited directly into the bone structure and goes right on shooting the powerful rays into the cells around it, would be more damaging than the comparable amount of radiation that was external to the body, would it not?

Dr. FRIEDELL. That is essentially correct. Of course, now we come to one point which is included on our outline—How do we make a decision as to whether certain radio elements are likely to be injurious, and how do we separate radiation coming from radioactive elements or radiation coming from cosmic rays or X-ray machines?

I would like to say this: That all particles or photons (electromagnetic radiation) which are energetic enough to produce ionization will produce the same kind of biological effects, roughly. There are modest differences, but in essence they would produce the same kind of biological effects.

How do we compare radio strontium, for example, with X-rays, or one radio element to another. Let's look at that first.

First of all, the half life of the element is very important. Will it last? Will it radiate a long period of time?—because this is going to determine what the dose is.

Another very important item is how energetic is this particle, and what is the range of this particle. This is tied in with its energy. So we have to know whether it is long lived, what kind of particle it produces, how energetic it is, what is its deposition in the body, will it deposit in vital areas or will it not deposit in vital areas.

These are the kinds of things we have to look at and examine in making any decision about whether a radio element will be serious or not.

Now, strontium 90 happens to fit some of these categories because it is a very long-lived material, and it deposits itself in areas which are vital to the economy of the organism.

Representative HOLIFIELD. Would it be inclined to deposit itself in concentrated areas in the bone, or diffuse through the bone structure?

Dr. FRIEDELL. It appears that strontium 90 is chemically very much like calcium. Therefore, as a good first approximation, we would assume, and I think reasonably conclude, that it distributes itself as calcium does in the bone, which is widely throughout the bone.

Representative HOLIFIELD. But in the case of a broken bone, for instance, that was being repaired, the tendency would be for it to concentrate during the repairing——

Dr. FRIEDELL. During the process of healing, we know there is more calcium deposited at the site of fracture, and, therefore, more strontium 90 would be deposited at the site of fracture.

Representative HOLIFIELD. We hear of bone cancer. Does that take place as a result of bombardment of strontium 90? Does that take place throughout the bone, or is it localized in certain areas of the bone, in the marrow, for instance?

Dr. FRIEDELL. Strontium 90, after you once introduce strontium 90 or, for that matter, almost any element that will seek the bone—and

we have gotten to use the term "bone seeker"—this will distribute itself more or less throughout the bones. Some have special depositions, but it is also the long continued radiation which does the damage. Therefore, it is a question of dose. There is evidence that no matter what radio element you use, if it is a bone seeker, and if it will radiate long enough to give a high enough dose, you will produce bone cancers—at high enough levels. That is what I would like to emphasize.

Senator HICKENLOOPER. Mr. Chairman?

Representative HOLIFIELD. Senator Hickenlooper.

Senator HICKENLOOPER. Doctor, is bone cancer a new thing?

Dr. FRIEDELL. Is it a good thing?

Senator HICKENLOOPER. A new thing.

Dr. FRIEDELL. No, sir.

Senator HICKENLOOPER. Is it something recently discovered?

Dr. FRIEDELL. No, sir.

Senator HICKENLOOPER. Have we not had bone cancer——

Dr. FRIEDELL. Bone cancer has been known almost since time immemorial.

Senator HICKENLOOPER. As long as we have had real medical knowledge?

Dr. FRIEDELL. I think so.

Senator HICKENLOOPER. Bone cancer occurred before we ever had any atomic tests or explosions, did it not?

Dr. FRIEDELL. Yes, it did.

Senator HICKENLOOPER. What would have caused bone cancer many years ago? Is that the absorption of certain nuclear particles, or does it come from some unknown activity of the cells as a starter?

Dr. FRIEDELL. I personally would hesitate to attribute this to the absorption of previous radiation or previous nuclear particles before we began the fallout tests. I think that on the whole this is related to some special biological factor that is yet unknown, and I hope we will hear a little later from one of the other witnesses about some of these special things that might contribute to the production of cancer in general.

Senator HICKENLOOPER. Yes. I mean we have heard a great deal about bone cancer since there has been some radiation released through bomb explosions, but I just wanted to at least assure myself that my belief was right that we had had bone cancer from time immemorial.

Dr. FRIEDELL. Yes, that is true. I will be glad to insert in the record the assertion that bone cancer has been present long before the tests began.

Representative HOLIFIELD. Our concern with strontium 90, though, is that it is an artificial element that is created by thermonuclear explosions and atomic explosions, and it is now a new factor, an additive factor, and experiments have proven that this new element which has been introduced is a cause of bone cancer. That is our concern, is it not?

Dr. FRIEDELL. This is true. But I think there is one very important point we have to look at very hard. That is, what are the levels of radiation? And what evidence do we have that these levels of radiation have produced bone cancer? And what are the bases for

assertions by some that bone cancers will be produced at very low levels in a small percentage of people?

Perhaps later, if I do not forget—I would be glad to be reminded of this—I would offer my humble opinion of this, because I have been looking at this as a radiologist for a number of years, and I am interested in this whole problem.

Representative HOLIFIELD. Why do you not discuss it now? We are on the question now.

Senator BRICKER. May I ask one question before he goes into that?

Representative HOLIFIELD. Yes.

Senator BRICKER. We know that radiation has a tendency to prevent the development of cancer in certain organs?

Dr. FRIEDELL. Yes, sir.

Senator BRICKER. And it is used for that purpose. Would there be any beneficial radiation that might come from strontium 90?

Dr. FRIEDELL. I would say that no radiation is for preventive purposes. I think radiation is used for curative purposes.

Senator BRICKER. For curative, palliative purposes.

Dr. FRIEDELL. Yes, sir.

Senator BRICKER. Would there be any of that effect come from ingested strontium 90?

Dr. FRIEDELL. I could see no benefit that might arise from deposition of radioactive elements.

Senator BRICKER. I have never heard it intimated, but I do know that radiation has been used in the cure of cancer, to help palliate the pain and prevent the growth.

Dr. FRIEDELL. Yes, sir. But in normal tissues I would be opposed, as a matter of fact, to the introduction of radioactive elements as a possible preventive measure.

Senator BRICKER. Of course, we all would. I would not want to take a chance. I wondered if there was any thinking along this line.

Dr. FRIEDELL. No, sir; I do not know of any.

Senator BRICKER. You have not heard it suggested.

Senator HICKENLOOPER. Mr. Chairman, along that line, I would ask one other question, if I may. That is along the line Senator Bricker is discussing.

Could there be any beneficial effect possibly flowing from the introduction of some of these radioactive elements, so far as a cancer that was in the process of formation, or growth within the system which came from other than causes which might have resulted from radiation?

Mr. FRIEDELL. I would say "No."

First of all, the levels of radiation—and again I want to emphasize this: We are talking about entirely different levels. To give you some idea of what the levels are to be curative in the case of cancer (incidentally bone cancer is an extremely resistant form of cancer, and radiation even in large doses is essentially ineffective), the doses that are necessary to cure cancer are in the order of five to ten thousand roentgens. The doses we are talking about, especially from the fallout levels, are in the thousandths of roentgens. So that we are not talking about the same order of magnitude at all.

Senator ANDERSON. I did not follow you on that.

Senator HICKENLOOPER. I think we have done quite a little experimental work in the radioactive iodine in thyroid, and cancer.

Dr. FRIEDELL. Yes, this is true.

Senator HICKENLOOPER. And at least some other attempted specifics along that line.

Dr. FRIEDELL. Yes, sir. In the case of radioiodine, certain cancers of the thyroid are very beneficially affected.

Representative HOLIFIELD. Mr. Van Zandt.

Senator ANDERSON. I want to clear up one thing first.

When you said from five to ten thousand roentgens, then you said the levels we are using here are "thousands" of roentgens?

Dr. FRIEDELL. "Thousandths." Decimal point zero zero one (0.001).

Senator ANDERSON. That is what I wanted. It was not very clear.

Representative HOLIFIELD. Mr. Van Zandt.

Representative VAN ZANDT. Dr. Friedell, in the event of a fracture with the presence of strontium 90, would the strontium 90 in any way slow down the mending of the bone?

Dr. FRIEDELL. I hesitate to answer that, because I have no specific information. But if I may conjecture, I would say it would be slowed down at very high levels of radiation, far above anything we have considered here. And I do not believe you could establish any difference in the growth rate at the kind of levels that are being talked about from fallout.

Representative VAN ZANDT. Then you cannot state whether a low dose of radiation would have any effect on the mending of the bones?

Dr. FRIEDELL. I would hesitate to propose that. I doubt it.

Representative HOLIFIELD. We recognize, Doctor, you are providing us the background statement, and others will go into these different facets.

Dr. FRIEDELL. Very well.

Representative HOLIFIELD. Will you proceed?

Dr. FRIEDELL. With regard to understanding what happens to the whole organism concerning the radiation syndrome, I think we have to look at what happens to the individual from the point of view of the systems that were injured. We try to point out a very cursory relationship between tissue sensitivity, the kind of effects that would produce, cellular effects where the economy of the organs was dependent upon these; and then we can look at some of the systems and pathological findings that might occur.

Since we know the gastrointestinal tract, and the hemotopoietic system are very sensitive to radiation, we can observe, with fairly large doses of radiation, symptoms and pathological effects that are directly related to these. The hematopoietic effect, of course, will appear as a severe drop in the white cells.

I will not go into the kinds of white cells. There are many more competent in this field than I, but this is generally true.

Some of the basic cells in the hematopoietic system are affected, which in turn affects the production of the platelets, which are tissue components in the blood required for the proper function of the clotting mechanism. These are seriously depleted, and under such circumstances you will get all kinds of bleeding tendencies. An individual who is heavily irradiated will show symptoms associated with the gastrointestinal tract, and with the hematopoietic system more or less simultaneously. In the doses that are high, the patient will become nauseated and vomit because of the immediate effects on the gastrointestinal tract, possibly also because some of the vital large

molecules are disrupted, so to speak, by ionization, which we point out can split some of these things up, and it may be these are circulating about and produce some of these effects.

So that an animal that is immediately irradiated in a very few hours may show nausea, vomiting, anorexia, severe diarrhea. This is directly related to what we can observe in the cells themselves, and in the tissue systems. There will be severe hematopoietic changes (the blood changes).

The organism has now lost its defense against infection, and infections will take over very promptly, and we can begin to observe in obvious areas the oropharynx, respiratory, and gastrointestinal tract, ulcerations and infection as a result of this injury to the tissue.

There will be little bleeding points throughout, as a result of interference with platelet formation. If they go on, the animal will be severely injured, and will die, partly as a result of these intercurrent effects, but also because we are unable to replenish some of the vital cells, or the body itself cannot replenish any of the vital cells.

This brings me to a point which we discuss not infrequently——

Representative HOLIFIELD. You are talking of large doses now?

Dr. FRIEDELL. I am talking of large doses in the order of 500 to 1,000 roentgens delivered to the individual.

This brings us to a point of how we might possibly protect the organism against radiation effects.

If we look at some of the very vital cells, it is reasonable to conclude that if it were possible to get these cells to be repopulated, possibly from an outside source, then the animal might be able to recover if the doses have not been really too large.

The recent efforts in this direction have been to get bone marrow cells introduced into the organism that has been heavily irradiated to see whether these cannot repopulate the hematopoietic system, at least until the cells themselves may have had an opportunity to recover.

Representative HOLIFIELD. This would indicate, from a practical standpoint, that you would have to have a bank of bone marrow cells for introduction into the system.

Dr. FRIEDELL. That is correct.

Representative HOLIFIELD. The same as you have to have a blood bank for transfusions?

Dr. FRIEDELL. This introduces many practical problems, and I am not sure it will have any place at all in attacking this problem.

Representative HOLIFIELD. I think it is important to bring this to the point of practical application, because a great many lay readers might think this could be a remedial measure which could be taken in a practical way. Of course, even transfusions would not be of any permanent lasting good if the spleen was affected.

Dr. FRIEDELL. Yes.

Representative HOLIFIELD. Or other blood producing organs.

Dr. FRIEDELL. Right. Essentially, if blood producing organs are seriously affected, it is doubtful if the transfusions have anything other than a transient effect. Generally, in doses of about 500 roentgens, which is presumed to kill, roughly, about half of the humans that may be affected by such a dose, supportive measures might be helpful, such as transfusions, replacing the fluid that is lost as a result of gastrointestinal injury. The use of antibiotics would be very effective be-

cause they would help to combat the infections occurring while the defenses were down.

Representative HOLIFIELD. From a remedial standpoint, this would be more valuable to those who had not received a lethal dose. To people, say, who received 100 or 200 roentgens, these measures would be of some value?

Dr. FRIEDELL. These measures may be valuable even at high doses, because it is possible—if 50 percent survive, say at 500 roentgens, it might be possible to push that up a little further, 60 or 70 percent. This is conjecture. We do not know. This is very important. When we get too high doses, over 1,500 roentgens, it seems that no measures are effective and we are unable to use any of these in any useful way.

Representative HOLIFIELD. Of course, from a practical standpoint, in an exposure of our people, it would be completely beyond the resources of the medical world to give this remedial treatment, would it not?

Dr. FRIEDELL. I think this could be true. But, if we are examining the whole problem, I think we would be overwhelmed by other things that would occur at the same time, and this would be essentially a small problem. There would be many, many more severe and difficult problems.

I have devoted my remarks primarily to the acute effects up to the present time, and we have talked about how we can assess these changes in the whole organism more or less immediately, and in fairly large doses.

It is well also to consider what would happen if the doses are lower, and if the animal survives. Is the animal completely unscathed if radiation has been delivered in smaller doses when comparatively few, or perhaps none have been killed?

Here I think we get into the problems that are very difficult to answer, and very difficult to prove effectively at the present time. This is an area where a great deal of study and research is required.

I would like to divide these, roughly, into three areas:

1. What is the effect on the vitality of the organism?
2. What is the effect on the production of malignant tumors?
3. What is the possible effect on future generations, the genetic effect?

The last I will speak very briefly upon, because many better speakers than I am will discuss it further. But I would like to say something about these points.

First of all, there is evidence indicated in animals with high doses—and by "high doses" I mean accumulation of many hundreds and even thousands of roentgens—that you can produce leukemia in susceptible strains.

I would like to point out that to produce leukemia a susceptible strain of mice must be used—that is, these mice must be such that they are genetically able to produce leukemia spontaneously. If the mice are not a susceptible strain—that is are not leukemia bearing—then the production of leukemia in such a strain is extremely difficult if not impossible. Thus one element that is essential is that the animal must have had inherent tendency to produce leukemia in the first place.

Secondly, tumors have been amply produced in animals with large doses of radiation, and tumors of all kinds. Whether it is strontium

90, phosphorus 32, or total body radiation, or radium, wherever you produce large doses and selective deposition in sensitive areas, you can produce tumors of all sorts. This is unquestioned.

Senator HICKENLOOPER. Benign, or other kinds of tumors?

Dr. FRIEDELL. Let us for the moment consider only the malignant tumors, tumors that will destroy the animal and fit all the criteria that people insist upon being characteristic of malignant, that is, they will spread to other tissues, and generally have the appearance of cancer. I think here is where we get into a problem.

If it is clear that there is evidence that tumors can be produced, and leukemia can be produced in various kinds of organisms under various conditions, it would be well to see if we could quantitate this. In other words, are there twice as many tumors produced when the dose is twice as high?

In general, this appears to be not well controlled, but there appear to be more tumors produced when the doses are higher. Under these circumstances, you can set yourselves up a little model or framework in which you show that the dose is related to the production of tumors, and the number of tumors.

Senator ANDERSON. Can I ask you there what you mean by "when the dose is high"? Can you give us the level again?

Dr. FRIEDELL. Yes. Generally, when we think of high doses, we think of doses in the lethal range, and perhaps I have been a little bit loose in this regard.

If you take animals that have been exposed to a lethal dose, 50 percent dose, that is, a dose in which 50 percent of the animals will succumb, and keep the survivors, the amount of radiation will be very high.

Senator ANDERSON. What I am trying to get to is this: We were talking previously about 5,000 to 10,000 roentgens.

Dr. FRIEDELL. Yes, sir.

Senator ANDERSON. Whereas, from fallout we are talking in thousandths, tiny fractions.

Dr. FRIEDELL. Yes, sir.

Senator ANDERSON. Now the things you are discussing, are they connected with fallout from nuclear weapons in any way, or an accumulation?

Dr. FRIEDELL. It is what we may be discussing, sir, and I would like to amplify this a little bit to show how this concept is approached. I will talk about those very low levels in just a moment.

Senator ANDERSON. All right.

Dr. FRIEDELL. In effect, what I am saying is large doses produce tumors and leukemia, and by "large doses," I am talking about thousands of roentgens, many hundreds of roentgens.

If you set yourself up a model in which you show that these doses will produce tumors and leukemia, and then extrapolate down to low levels, especially on the basis of how the data looked at high levels, you can begin to conjecture that perhaps these lower levels could in a very small percentage of patients or individuals produce these kinds of tumors.

Now, I think what we need to look at, and what this group is going to look at in the next couple of days, is how good are these extrapolations—Is this conjecture? Is this soundly conceived?

I wish I could offer an authoritative statement right now to end all of this discussion, but unfortunately I cannot. However, I would like to say this: That I am concerned about the fact that there are no data at the very low levels. It is just nonexistent. Much below a hundred roentgens, or 25 roentgens in the case of mutations, we have no data.

Representative HOLIFIELD. You are speaking of man?

Dr. FRIEDELL. In animals as well. I am speaking of all complex biological systems.

Representative HOLIFIELD. Have not you been able through following mice, for instance, through several generations, to establish any data of this type?

Dr. FRIEDELL. Yes, but these have been in large doses. These have not been in hundredths, or tenths of roentgens, they have been in doses far larger.

One of the reasons we are using large doses is that you have to have some kind of statistical security in looking at the information. To discover an effect which would occur once in 10,000 times, you would require an inordinate number of biological specimens, and so on.

But I would like to point out that this difficulty exists, and for this reason we do not have really secure data.

Now the people who propose that the doses at very low levels can produce effects have pointed out the data at higher doses are such that permit them to make these extrapolations, and there are many ways of looking at this. You can do it mathematically, you can do it by examing the mechanism by which these effects are produced, and in this way kind of develop some hypotheses which will permit you to make some conclusions.

I feel that the data at the very low levels are based on this kind of hypothesizing, and therefore, correctly are not available at the present time, and perhaps will not be available for a long, long time because of the difficulty.

We should, therefore, be slow in accepting these if we need to use it for a vital decision.

I think at the present time these data are not good enough to make very extreme or vital decisions in this regard. I think all of us should look at this to see what is the truth of the matter and what scientific evidence we can find which will permit us to make these conclusions.

Senator ANDERSON. May I try to translate that to myself and see if I got it correctly?

Dr. FRIEDELL. Yes, sir.

Senator ANDERSON. Do you tell us the data are not now good enough for the Congress, for example, to reach a decision on whether continuation of tests at the present level is wise or unwise?

Dr. FRIEDELL. I would say that, sir. I do not believe the data at the present time are good enough to make conclusive decisions.

Senator ANDERSON. If it is not good enough for the Congress, it is not good enough for the Atomic Energy Commission, either, then, is it?

Dr. FRIEDELL. Let me revise that statement.

Senator ANDERSON. That is the trouble. If it is not good enough for the Congress to reach a decision, it does seem to be good enough for the Atomic Energy Commission to reach a decision. They can sit in their ivory tower and say, "This is all right," but to get back to

the Congress which is having to deal with human beings, the data are not good enough.

Dr. FRIEDELL. I would say the data are not such as to suggest any vital or important decisions which would alter the course being pursued at this time.

First of all, they are not good enough to be conclusive, and there are other reasons I will go into further, which would make me have reservations on what they mean in general.

One of these is, when talking about these doses we are talking about the levels which fit into the dose levels we are receiving right now. If you are interested in numbers, each one of us are receiving or having about 3,000 to 5,000 ionizing events per cubic centimeter per second. Now it is 10,000, now it is 15,000, something of that order. So there are a lot of ionizing events going on now. We are living in a sea of radiation rising from various things, and this will be discussed, I am sure, or has already been discussed.

Senator ANDERSON. I think that is a very useful statement, and I appreciate it. I am only trying to say, if it is difficult for the Congress to get any satisfactory or conclusive answer from the existing data, that it must be equally disturbing, I would think, to the Atomic Energy Commission if they want to take a fair look at it. That is my only point.

Dr. FRIEDELL. I would think—if I were going to conjecture again, on how they are looking at it. I think they are disturbed by this, and I think their examination of the data would suggest to them there is no reason to stop these tests because of the levels of radiation. The levels are apparently at levels which are far below levels which we have established as being the acceptable doses, and are quite within the range of radiation occurring at the present time all around.

Senator BRICKER. Mr. Chairman?

Representative HOLIFIELD. Senator Bricker.

Senator BRICKER. Is there any thinking along the line that, if there were no background ionizing radiation at all, the human body would be devoid of cancer?

Dr. FRIEDELL. I do not have any opinion about this, sir. But again I will conjecture that I think the cause for malignant disease lies in some biological derangement that is really not related——

Senator BRICKER. To radiation?

Dr. FRIEDELL. Alone.

Senator BRICKER. But ionization of the cells?

Dr. FRIEDELL. Right.

Representative HOLIFIELD. You used the word "alone"; it is not related alone to that point. You think there may be other causes? I was afraid that word was missed by the audience. I think it is important.

Dr. FRIEDELL. I think at the proper levels, high enough levels, these effects can be produced. At the very low levels where the levels begin to approach the natural levels we are facing, I think there is grave uncertainty. This, of course, is concerned with the whole concept of whether the effects will be occurring at low levels in the same rate that they are occurring at high levels, and whether there is such a thing as threshhold. In other words, is there some level below which nothing will happen?

Again, this is very difficult to establish. The evidence, as I see it, is inconclusive in this direction, and if I had to choose, if I had to make a decision now, if I were compelled to make a decision, I would hesitate to accept this concept that a threshhold does not exist.

Senator BRICKER. That is the reason I asked the question, frankly. It is your thinking, then, that there is a biological cause of these abnormal growths in the human body?

Dr. FRIEDELL. I do, sir.

Senator BRICKER. Above and beyond and separate from the radiation?

Dr. FRIEDELL. Yes; I do.

Representative HOLIFIELD. Will you state your observation in an affirmative way rather than a negative way? And then tell me if you apply that equally to somatic as well as reproductive cells.

Dr. FRIEDELL. I sort of left out the reproductive aspect of this.

Representative HOLIFIELD. That is just what I thought maybe you left out. That is why I wanted you to restate it.

Dr. FRIEDELL. I would say, from the point of view of production of tumors, and leukemias, I would hesitate to accept the concept that a threshold does not exist. From a point of view of genetics—now I am in a field where I am even less familiar—I think the data are not unassailable, but I think they are stronger than they are in the concept of cancers or leukemias.

Again I would like to point out the data on mutations and genetic effects do not exist below 25 roentgens.

The basis for making these decisions is careful study of the data, by protracting the radiation, by fractionating it, by observing the effect of dose, and this gives them a line which can be extrapolated down below. I have no objection to these extrapolations, and ever since Descartes introduced the coordinate system, this is a privilege of all. I do not really understand whether these things necessarily follow this rule. I would think I would want a much better and much more carefully controlled examination of the effect at very low levels.

Representative VAN ZANDT. Mr. Chairman?

Representative HOLIFIELD. Mr. Van Zandt.

Representative VAN ZANDT. Dr. Friedell, to be conclusive, would you go into a little more detail as to what must be required?

Dr. FRIEDELL. What must be required?

Representative VAN ZANDT. Yes.

Dr. FRIEDELL. As far as our studies go?

Representative VAN ZANDT. Yes.

Dr. FRIEDELL. I think probably the most important thing is to look at the basic aspects of what occurs in biological systems, so that we can understand the mechanism, so that we can see whether once we understand this mechanism it fits in with the data which we already have. And here I feel is where the greatest possibility for really learning something about it exists. I would like to see this emphasized over and above the efforts to perhaps use 10 million mice at very low levels. I would think that basic studies of biochemical effects, the possible way in which these things occur, would contribute more than doing such statistical studies——

Representative VAN ZANDT. Would you apply a time factor?

Dr. FRIEDELL. I would hesitate to apply a time factor, but since I am making all sorts of conjectures, I will add one here.

I will say that perhaps in 5 to 10 years we would have a much better understanding of this.

Representative HOLIFIELD. Of course, if your understanding at that time had to be revised downward as the chart this morning has been revised downward, we would be dealing then with an accumulation of substance which would be ineradicable, and we would have it; would we not?

Dr. FRIEDELL. Yes.

On the last page of my little statement, I tried to put these things together. I think two problems exist.

First of all, I think there is a problem of examining the data scientifically to know where the truth lies.

Assuming the correct consequences of this, assuming no threshold, and all radiation is injurious and produces some effect, I think we have to fairly assess this kind of hazard compared with the hazard which now exists. I do not feel we have yet really looked at this in an unbiased and nonemotional manner. I think it can be done, especially if we look at it over a long period of time so we do not rush into any important decisions at this time.

Senator BRICKER. You have discussed the control of abnormal growths, the cause of them, the somatic effects in a limited way. What have you to say about the length of life?

Dr. FRIEDELL. Here again I do not have any good, well-founded opinion. The data that are available indicate that for large doses in animals, there is a decreasing survival due to all the causes that would occur ordinarily in these animals. In other words, they die of various things, only these various causes of death appear a little earlier in heavily irradiated animals.

Again the same problem exists. Can you extrapolate down below?

This figure we heard earlier that somebody will have suffered a loss of 20 days in survival. It seems to me there can be no data at this level, because this would require an inordinate amount of animals at very low levels to establish this, and I just do not have that kind of sureness about studies in which you observe one event in hundreds of thousands of others.

From the point of view of the span of life, I feel for projections to low levels this falls in exactly the same kind of category. We cannot determine what is happening at very low levels.

I think I can understand the reasons and conjectures and hypotheses of people who propose that this occurs, but they make me uneasy, and I am loath and not ready to fully accept them. I think they are not incontrovertible.

From the point of data on humans, there is some published evidence to show a radiologist may, by the nature of his activities, have received more radiation than others. I am a radiologist myself. I turned some data recently published over to the statistician, and he wrote me a letter saying that these data were suggestive, but by no means conclusive. And the way in which you sample the various groups makes a tremendous amount of difference, and even though averages of the compared group, for example, might be the same, the distribu-

tion could make a tremendous difference. I know this has been touched upon by others who feel the same way.

Representative HOLIFIELD. We found that averages are a little bit unreliable to rely on in some instances.

Dr. FRIEDELL. Yes.

Representative HOLIFIELD. Thank you very much. Are you planning to stay the rest of the day? We might have you on in the discussion late this afternoon.

Dr. FRIEDELL. Yes, sir.

Representative HOLIFIELD. Thank you, sir. Your prepared statement will be placed in the record at this point.

(The prepared statement referred to follows:)

MATERIAL PRESENTED BEFORE THE JOINT COMMITTEE ON ATOMIC ENERGY BY H. L. FRIEDELL, M. D.

The biological effects that are observed when tissues are irradiated must begin as a result of the physical interaction of ionizing radiation and the atoms that comprise the biological specimen.

This interaction appears primarily as ionization—that is, ejection of an electron from the orbit by excitation, in which the energy level of the electron without ejection probably also plays a part.

The excited and ionized atoms and molecules then appear to interact in various ways, eventually producing profound chemical and biochemical change. The immediate physical and chemical changes are probably over in fractions of a microsecond, or at most a few microseconds. The biological effects may not appear for hours, days, or months.

One interesting aspect of this energy absorption is that only a small absorption of energy produces such widespread biological effects. One thousand roentgens, a lethal dose, involves only a very small fraction of a calory per gram (2×10^{-3} calories per gram). Another way to look at this is that the energy which is absorbed appears to affect directly only about 10^{7} molecules in a cell which generally contains 10^{14} molecules.

In outline form, we need to think of the chain of events as (1) physical interaction, (2) chemical and biochemical changes, (3) cellular changes, (4) going on to tissue and organ system alteration, and, finally (5) injury to the whole organism.

The chemical and biochemical effects which occur are at the present time somewhat obscure and receiving much study. One of these effects that has been of interest and which appears to be tied up with some of the observable biological changes are the indirect effects resulting from the disruption of the water molecule abundantly present in living tissue. In the presence of oxygen, this results in producing highly active water radicals which in turn attack vital molecules in the cell since they are very active oxidants.

It has been found that, by depriving the cell of oxygen during the radiation period, these effects can be markedly minimized. By introducing chemicals which are in themselves oxygen acceptors, the oxidation effect on sensitive tissue systems may be spared and the radiation injury is markedly minimized.

At the present time, the best working concept is that the indirect effects are very important at the levels of radiation with which we are concerned (500 to 1,000 r.), that efforts to correct or prevent the chemical and biochemical disturbances as a result of disruption of the water molecules protects biological systems in an effective manner. It should be pointed out that this must be done during the radiation and is completely ineffective after the radiation has been delivered.

The cellular effects have been quite thoroughly studied. On the whole, the nucleus is known to be more sensitive than the cytoplasm. Cells appear to be affected primarily with respect to their function of division and recent studies have, therefore, been directed at this aspect. From the biochemical point of view, the nucleic acid metabolism, and particularly DNA in the nucleus, has received considerable attention.

From a general point of view, it is best to look at the cellular changes and try to understand the difference between cells and their place in the economy

of the whole organism. At one end we have extremely sensitive cells. These may be listed as follows:

(a) Extremely sensitive: Lymphocytes, erythroblasts, germinal epithelium of testis, myeloblasts, germinal cells of ovary.

(b) Highly sensitive to moderately sensitive: Epithelium of intestinal crypts, basal layers of the skin.

(c) Insensitive: Connective tissue, bone, liver, pancreas, kidney, nerve, brain, muscle.

An estimate of the variation in sensitivity permits us to understand better the effects on tissue and on the whole organism. The effect on the whole organism is obviously determined by how dependent the organism is upon extremely radiosensitive tissues. Since the hematopoietic system is one of the extremely important tissues upon which the organism vitally depends, it can be explained that irradiated animals can be readily injured by comparatively modest doses. The animals suffer infections and will die a hematopoietic death if some measure for correction is not instituted. The epithelium of the gastrointestinal tract is less sensitive but nevertheless readily affected by large doses of radiation. At the lower dose levels there is rapid recovery. At the higher dose levels recovery is markedly impaired and the animal may succumb to what is known as a gastrointestinal death, sometimes even before the hematopoietic changes can manifest themselves.

Many tissues are quite unaffected by radiation at levels which would cause death of the whole organism. Therefore, under certain circumstances, particularly when certain radio elements are used, considerable radiation may be delivered without seriously affecting the organism as a whole since the radiation is confined to a comparatively insensitive structure. Also, radiation delivered to sensitive tissues which may not be vital to the organism proper will have comparatively little effect on the individual. As an example, radiation delivered to the thyroid, which in older individuals is comparatively insensitive to radiation, will not produce any appreciable effect on the whole organism. Also, radiation delivered in modest doses to the gonads may produce sterility but will otherwise appear to have no demonstrable effect on the individual proper.

It would be well to point out that the manner in which radiation is delivered is highly important in considering the possible biological effects (excepting genetic changes which will be discussed briefly later). Protraction and fractionation of the radiation markedly reduces the total somatic biological effect. Radiation delivered to specific parts of the body markedly alters the response so that shielding of part of the body increases the dose necessary for lethal effects.

Generally, radiation delivered over a long period of time gives some of the tissues an opportunity to recover (a process which is poorly understood) and, therefore, increases survival.

Specifically, it is well to point out that species sensitivity varies among mammals. Following is a list which gives some concept of the range that may exist:

LD_{50} dose:	*Roentgens*	LD_{50} dose:	*Roentgens*
Guinea pigs	200	Rats	700
Pigs	300	Hamsters	750
Dogs	350	Rabbits	800
Mice	450	Bacteria	100,000
Monkeys	500	Viruses	1,000,000

Man is estimated to fall somewhere halfway through this range of mammals and the LD_{50} dose (that is, the dose necessary to kill 50 percent of the individuals) is presumed to be about 500 roentgens.

As a result of whole-body radiation, certain specific tissues effects are produced. These in turn determine the clinical syndrome. Briefly, the effects which first appear are nausea and vomiting, which can be explained on the injury to the gastrointestinal tract. Prostration, diarrhea, and anorexia may promptly occur with larger doses—again the result of interference with gastroitestinal function and dehydration. The blood forming tissues are simultaneously affected, but evidence of their severe depression is slightly delayed. There is marked depletion of the white cells—later the red cells. The elements involved in clotting are seriously affected and hemorrhages as a result of this derangement soon appear. The individual is susceptible to infection for two reasons—one, depletion of the white cells, and secondly, by impairment of the ability to form antibodies. As a result of this susceptibility to infection, the

oropharynx, respiratory and gastrointestinal tract are prone to ulceration and infection. The central nervous system is essentially not affected.

The neuromuscular system and the specific function of the liver and kidney appear not affected at lethal doses, fitting in with our general concept of radiation sensitivity of tissues. Epilation occurs as the dose approaches the LD_{50} range, since the basal cells of the skin and their derivatives are quite sensitive.

Of concern also are effects which do not appear immediately as the result of radiation but are either postponed until late in the life cycle of the organism or may be observed only by special methods of testing. One of these is the question of general impairment of viability of the organism which may be susceptible of determination by observation on longevity.

In animals at fairly large doses there is good evidence that animals do not survive as long as nonirradiated controls. Whether this may be extrapolated to low dose levels is uncertain and is by no means conclusively established. There are no good data at levels of less than 100 roentgens and those that are available do not indicate any change in longevity. Recently, there has been presented evidence that radiologists who, having received more radiation than others by the nature of their activities, have suffered a reduction in their life span. Although the data are suggestive, statisticians have seriously questioned the significance of these data because of the method of sampling and of the uncertain relationship of the age groups.

Another late consequence of radiation in which the animal survives is the production of malignant new growths (tumors of various kinds) and leukemia. In animals, large doses unquestionably produce an increase in the incidence of cancers and leukemias. It should be pointed out that it is necessary to use a susceptible strain and that in certain insensitive strains it is not possible to produce these changes. The question as to whether this occurs in man, I think, has been amply demonstrated.

I believe there is evidence to show that when humans are heavily irradiated, tumors and lukemia will appear. The question is whether this occurrence may be satisfactorily quantitated and attributed to low levels of radiation. We have no data in this respect. Theoretically, considerations suggest that this may occur, but at present are entirely in the realm of hypothesis and must be considered inconclusive.

A third important late effect is concerned with the injury to the genetic tissue of the organism, and here I believe we should now make a distinction between sterility and genetic alteration.

The cells of the gonads which develop into sperm and ova and concerned with reproduction are extremely sensitive—comparable to that of hematopoietic tissue, and are injured with modest doses of radiation. From the point of view of sterility, it requires about 300 to 400 *r* to induce sterility in the female and perhaps 500 *r* to induce sterility in the male—that is, there is essentially complete loss of viability of the reproductive cells so that no progeny is possible.

This must also be distinguished from injury to the cells in the reproductive organs having to do with sexual characteristics—that is, male and female characteristics and other hormonal influences. These cells are not readily injured by radiation and are comparatively insensitive. Although it is easy to produce sterility, it is very difficult to eliminate the normal sexual characteristics—that is, male and female characteristics and other related functions.

The important change which has significance for all of society concerns itself with the alteration of the genes proper. Without going into the concepts of physical characteristics of the gene and its position in the reproductive apparatus, it is sufficient to say that these alterations are known as mutations which are essentially uninvolved in the reproductive capacity of the individual but produce its effects in subsequent generations.

Briefly, these mutations as a result of radiation appear to be similar to mutations produced by other causes. (Radiation is not the only cause for mutation.) The number of mutants appears to be directly related to the amount of radiation; that is, doubling the dose doubles the number of mutants. It is presumed that the radiation would have exactly the same importance and effect no matter how low the radiation level. It should be pointed out that we have no data below 25 roentgens and that extrapolations to very low levels are made on theoretical grounds.

It has also been generally accepted that the radiation effects on the extent of mutations are cumulative. That is, whether the dose is given at one time or distributed over long periods of time, the effects are exactly the same. Although

these data appear sound, they may still be considered incomplete and there are minor discrepancies which have appeared and which may require some elaboration. There is also reason to discuss the place of the production of mutations compared with the general mutations that are being retained in the genetic pool.

The radiation dose necessary to double the mutation rate appears to be about 50 roentgens. It should be clearly understood that this is an estimate, and competent geneticists have submitted proposals from 5 to 150 roentgens.

It is known that there are many diseases of heredity (that is, genetic origin) which are almost certainly the result of mutants and may therefore be examined in the same light as mutants due to radiation. Since these may be retained in the pool because of the amelioration of the rigors of selection, it would be possible to assess all of these mutants in terms of roentgens. Therefore, a better estimate of the total hazard as a result of low doses of radiation would be possible.

It appears that most mutations appear to be of the recessive variety which would therefore, in effect, not permit their immediate recognition or elimination until after many, many generations. This means that the mutant will become widely disseminated in the genetic pool. It also means that the radiation received by a small segment of society may be of little consequence since the radiation to the total population would be roughly the ratio of the total population to this small segment. The genetic effects are best surveyed from the point of view of its effect on the whole population and, generally speaking, the genetic effects become significant when delivered to either the whole population or large segments of it.

I am inclined to make these observations from the point of view of long-term effects of radiation—that is, the production of tumors, leukemia, and the decrease in longevity.

All data presented at the present time are either presumptive or speculative for very low doses. They rest in hypotheses derived from the theoretical aspect of dose effects at high levels. I believe there is sufficient uncertainty so that it would be unwise, and in fact nonscientific, to make conclusive decisions on the basis of these extrapolations.

With respect to the genetic effects, which have been extensively studied by biologists, there are sufficient uncertainties even in these data so that it is not possible to accept them as entirely unassailable. These include the fact that data at low levels do not exist, that data are confined at present to Drosophila and to a few small mammals such as mice, that the mutation rate due to ultraviolet radiation appears to be nonlinear, and there is reason to believe that some of the energy transfer with ionizing radiation is in part of the same character as that with ultraviolet radiation. Man has existed since time immemorial in a sea of radiation where fairly large differences because of altitude and special geographic places also are present. It is difficult to reconcile some of the conjectures to be made at very low levels with the natural radiation doses to which man has already been subjected.

To my mind, the problems of biologic effects at low doses are in essence these:

1. The data on the biological effects at low levels of radiation are by no means conclusive. At best they must be considered highly presumptive This suggests that extensive, carefully considered research is necessary.

2. Even if one assumes that the low-level effects of radiation are established, the problem of establishing the hazard and the risk rate at these levels has not yet been fully and properly evaluated. With specific regard to the fallout problem, it is my opinion that at the low levels which now appear to exist, no immediate decision on any vital problems is now necessary.

With respect to the general overall consideration regarding all-out nuclear warfare, a different order of magnitude is introduced and I must join with others in pointing out that this is fraught with the direst consequences, and that every effort must be expended to the elimination of nuclear warfare.

With specific respect to the fallout problem, it is my opinion that with the low levels which now exist, no precipitate alteration in our course is required. There are a number of organizations on radiation protection that are continually looking at this problem with representatives of all disciplines, and they are gradually modifying the acceptable levels wherever it is found desirable.

Representative HOLIFIELD. Before we hear our next witness, I would like to insert in the record a report from the Armed Forces Institute of Pathology.

(The report referred to follows:)

ARMED FORCES INSTITUTE OF PATHOLOGY,
WALTER REED ARMY MEDICAL CENTER,
Washington, D. C., May 16, 1957.

Subject: Statements for congressional hearings.
To: Chief of Research and Development, Department of the Army, Washington, D. C.
(Attn. Chief, Atomic Division.)

The following report is submitted in accordance with a verbal request to the Director of the Armed Forces Institute of Pathology from Lieutenant Colonel Ransom of the Research and Development Office of the Department of the Army, May 14, 1957. The time limit of 24 hours for the preparation of such an extensive report, and the absence on TDY of the Chief and Assistant Chief of the Section on Radiobiology, Armed Forces Institute of Pathology at the Nevada test site on Operation Plumbob 4.1 necessarily resulted in some limitation on presentation of material requested which under more favorable circumstances could possibly be more fully covered. The discussions and answers as presented represent a combined effort of the professional staff of the Armed Forces Institute of Pathology with some assistance obtained from Naval Medical Research Institute and Walter Reed Army Institute of Research.

W. M. SILLIPHANT,
Captain, MC, USN, The Director.

CONCERNING TOPIC IX

A detailed discussion of the occurrence of strontium 90 and cesium 137 in the atmosphere and its uptake and behavior in man is contained in the remarks prepared by Dr. Willard F. Libby, Commissioner, United States Atomic Energy Commission, for delivery before the spring meeting of the American Physical Society, Washington, D. C., April 26, 1957. A copy is attached (see p. 1519). These findings have also been discussed and confirmed by Drs. J. L. Kulp, W. R. Eckelmann, A. R. Schulert (Strontium 90 in Man. Science, 125, p. 219, February 8, 1957). However, Dr. Lapp (Science, vol. 125, p. 933, May 10, 1957) criticizes some of these conclusions, and points out some pertinent factors for consideration. His critique is attached (see pp. 694, 704).

CONCERNING TOPIC X

SOMATIC EFFECTS—PATHOLOGY

A. Distinction must be made between the somatic and genetic effects of radiation

The genetic cells carry on from generation to generation the damage which has been received. The somatic cells receive the injury but this is not transmitted from one generation to another. The effects of high level radiation may be manifested not only immediately but also after a delayed period. There are also effects from a low level of radiation and some organs are more readily injured than others.

B. Early effects of exposure of animals and man to external radiation

1. *Gama and X-radiation.*—Syndrome of radiation sickness. Individuals receiving doses of total body radiation can probably be best divided from a standpoint of prognosis according to the clinical signs and symptoms they present. This is particularly true because of individual variation in the response of different people to the same dose of irradiation. Roughly, casualties may be grouped into those in which survival is improbable, possible, and probable.. There is, however, no very sharp line of demarcation among the groups. The signs and symptoms have been described for the Japanese casualties at Hiroshima and Nagasaki in a report by Liebow, Warren, and DeCoursey in the American Journal of Pathology and in a report entitled "Some Effects of Iionizing Radiation on Human Beings" involving particularly the Marshallese casualties. In doses of more than 3,000 roentgens one may encounter a hyperacute reaction within an hour whereas in the range of about 3,000 to 2,000 roentgens nauseau, vomiting, and some diarrhea and fatigue may be the initial reaction in 2 to 4 hours after exposure. In individuals receiving doses between the range of 2,000 down to 800 roentgens there may be a period of relative well-being following the initial reaction for a few days and then a gradual return of

anorexia, malaise, severe diarrhea, thirst, fever, delirium, and leucopenia. In individuals between 800 and 300 roentgens this reaction may come in about 2 to 3 weeks with acute bone marrow failure, ulceration of the gastrointestinal tract, epilation, and bacterial infection. A subacute reaction consisting of subacute marrow failure, subacute infection in the lungs, brain, and bowel and general malnutrition may manifest itself in about 6 weeks after exposure in patients receiving 350 to 250 roentgens. In those receiving less than 250 roentgens and in some survivors from doses in the lethal range, there may be a chronic reaction of varying degrees extending for a period of months or longer of malnutrition, chronic anemia, premature aging, leukemia, and possibly neoplasia. The above acute syndrome varies with the geometry of the source of radiation in relation to the exposed person.

(*a*) Marshallese: See reference.

(*b*) The Los Alamos incidents referred to under X, B, 1, b are covered in a single entire issue of the Annals of Internal Medicine February 2, 1952.

2. *Beta radiation—Beta burns.*—As long as only very penetrating radiations are involved in exposure of the entire body, skin injury would rarely be a problem, because a dose sufficient to permanently affect it would kill the patient before dermatologic lesions were of any concern. Epilation is an exception to this statement since it was present, though only temporarily, in some of the Japanese atom-bomb victims. During fallout from bomb clouds, however, radioactive particles may settle on the exposed skin of anyone outdoors, and the hazards of beta particle radiation burns are added to the effect produced by penetrating gamma rays. Beta particle burns resulting from fallout first came into public prominence with the announcement that some of the inhabitants of the Marshall Islands were exposed to such a hazard during the 1954 weapons-testing program. However, the problem of fallout was not a new thing to those charged with the responsibility of conducting tests of nuclear weapons. At the time of the first nuclear detonation at Alamagordo, N. Mex., a number of cattle about 10 miles from the blast received fallout on their backs. The fine particles were retained by the hair, and in a few weeks epilation and blisterlike lesions occurred. The lesions healed much like ordinary thermal burns, and the hair grew again, but the original red color was replaced by grey or white. Late effects of this exposure have recently been reported in studies conducted at the AFIP.

(*a*) Marshallese: In the Marshallese group individuals were exposed to gamma and beta radiation. The injuries due to beta burns were local and confined to the areas of contact. The reaction manifested itself by initial tingling and itching at the time of exposure, followed by erythema and edema in a few hours, lasting for 2 to 3 days. There was then a latent asymptomatic 3- to 5-day period with a return of secondary erythema with vesicle formation. Drying and desquamation takes place in about 3 weeks and the individual then may enter a chronic phase with some atrophy of the involved parts taking place. Where both types of radiation occur concomitantly, the gamma radiation generally overrides the beta in clinical significance.

The effects of ionizing radiation amongst the Marshallese has been extensively covered in the report Some Effects of Ionizing Radiation on Human Beings from the Naval Medical Research Institute, Bethesda, Md.; United States Naval Radiological Defense Laboratory, California; and Medical Department, Brookhaven National Laboratory, Upton, N. Y.; United States Atomic Energy Commission, July 1955. Values for gamma and beta radiation could only be approximated but there was a high enough dose on the skin to produce lesions. The estimated "point source" doses were:

Rongelap, group I, 260 r.
Uterik, group IV, 20 r.

Some of the patients showed acute symptoms of diarrhea and vomiting and itching and burning of the skin in group I (Rongelap) but none in group IV (Uterik) showed these symptoms. Biopsies were taken of the skin at various stages. These showed changes typical of radiation reaction. Ultimately there was complete restoration of the skin.

(*b*) Other examples: Skin lesions, acute, chronic and neoplastic were one of the earliest hazards to be recognized in human beings exposed to low energy radiation. Human casualties from ionizing radiation have been of increasing concern since the turn of the century. These include in addition to skin lesions, a higher incidence of leukemia among radiologists than among the general population. The occurrence of cataracts among early workers with cyclotrons, the

high incidence of cancer of the lungs as an occupational hazard among certain miners in Czechoslovakia, and the bone cancers that occurred in watch dial painters in this country.

(c) *The early effects of internal radiation are dependent upon the amount, type, and area where material is deposited*

If the material is insoluble and taken into the gastrointestinal tract, it might produce only local irritation of the intestinal tract but not be absorbed within the body economy. Another example would be in giving I–131, the early manifestations of which would be some soreness of the thyroid and hematopoietic changes (approximately 2 to 3 weeks). However, this would require a large therapeutic dose.

(d) *Criteria include*

Half life (the physical and biological half lives), body utilization, solubility and excretion.

(e) *The degree to which late effects, readily produced in animals by single "massive" doses of total body ionizing radiation, may turn up in survivors in Japan is still under investigation*

Such effects include the occurrence of tumors in various organs after long latent periods following a single exposure to total body radiations in the lethal dose range; genetic mutations that affect subsequent generations; and aging. Such injuries are obviously far more difficult to follow in man than in controlled laboratory animal populations. It is only very recently that quantitative data on genetic mutations have been extended from fruitflies to a mammal, namely, the laboratory mouse, and this may still be a long way from the problem in man. An increased incidence of myelogenous leukemia and radiation cataracts has been found in the followup studies of the Japanese to date.

In the course of radiotherapy, it seems that serious late effects can result from a single exposure or a series of exposures to X or isotopic radiations. Thyroid cancer has resulted in children being given X-radiation for thymic disease. Leukemia has also been reported in individuals receiving X-radiation for spondylitis or those receiving repeated I–131 for cancer. The increased incidence in leukemia in the Japanese exposed to nuclear explosions at Hiroshima and Nagasaki is the only example of this disease occurring in man after a single acute exposure of the entire body to ionizing radiation.

(f) *General*

Exposure of the entire body, or a major portion thereof, to significant amounts of penetrating ionizing radiation interferes with the proliferation of normally self-replenishing tissues essential to life, namely the bone marrow, and under certain circumstances, the small bowel epitheliu. Within the lethal dose range, most of the stem cells responsible for the continued replacement of these tissues are still capable of recovery, with survival being dependent upon the time and extent of regeneration. The acute radiation syndrome, therefore, is a clinical entity resulting from an action of ionizing radiation from which recovery is potentially possible. It is a diagnosis that includes the signs and symptoms that evolve following exposure of the whole body or a major portion thereof to penetrating ionizing radiation.

It has been estimated that the human bone marrow pours into the blood stream each day 1 trillion red blood cells, 10 billion granulocytes and 500 billion platelets. The epithelial lining of the small bowel of a rat is replaced every day and a half. In the human, the rate of replacement is not accurately known, but it is also quite rapid. The rate of cell division in these tissues, throughout life, is as high as that encountered in a great many malignant tumors. Interference with the continuous proliferation or replacement of these tissues results in a secondary aplastic anemia and damage to the integrity of the alimentary tract.

The sequelae of panhematocytopenia from any cause have been known for a number of years. They include (1) thrombocytopenic purpura, (2) anemia, and (3) agranolocytic infections.

Anemia is due to a variety of factors including (1) inadequate hematopoiesis, (2) widespread purpuric hemorrhage, and (3) increased destruction of red blood cells. Hemorrhage is most prone to occur at sites of injury due to radiation damage, accidental trauma, and physiologic activity. Huge numbers of extravasated erythrocytes return to the bloow stream via the lymphatic system and thoracic ducts. Many are phagocytized by macrophages. Increased destruc-

tion of red blood cells occurs, and leads to increased deposits of hemosiderin in the spleen.

Vincent's Angina is a common complication of agranulocytosis from any cause. Mechanical trauma and poor oral hygience invite septic ulcerations, particularly in the presence of agranulocytosis. The tonsils, as is well known, may serve as portals of entry for bacteria with the subsequent development of a bacteremia or septicemia.

Focal hemorrhages from radiation-induced thrombocytopenic purpura may be followed by septic ulcerations of the large bowel and the onset of diarrhea several weeks after exposure, even though the dose of radiation to the abdomen has not been sufficient to permanently interfere with recovery of the more radiosensitive small bowel. Such things as focal hemorrhages, delayed vascular reactions to irradiation, and to injured tissue, damage to the solitary lymphoid follicles and smoldering superficial infections contribute to the development of such ulcers.

Recovery of the small bowel epithelium generally occurs following exposure to total body ionizing radiation up to 100 percent lethal dose. Failure of recovery, however, may be an important factor in early deaths resulting from exposure to supralethal doses, or where the small intenstine is the principal site of injury.

1. In the various mechanisms of response of man to radiation the injury is caused by the energy imparted by the various ionizing radiations. This energy is dissipated in matter through excitation or ionization, depending upon the energy level of the radiation. The total ionizing action is related to the number of ion pairs formed per unit limit. This may be expressed as the density of ionization. Alpha particles have a high ionization density but a short range; beta particles a less dense ionization pattern but a range of a few millimeters in tissue and a few centimeters in air. Gamma radiation has a long range with the lightest ionization density. Neutrons have a somewhat shorter range than gamma rays. This is significant in that gamma and neutrons can penetrate with ease into the body from external sources. In contradistinction, alpha and beta particles are limited in such penetration from practically 0 for the alphas to a few millimeters through the skin for the betas. However, from an internal source, alpha emitters take on particular importance because of their unrestricted local activity over very long periods of time.

Certain effects of ionizing radiation on living cells in both plant and animal tissues have been clearly established for many years. These include (1) acute cell destruction, associated with nuclear vacuolization, rupture, and fragmentation; (2) a variety of chromosomal alterations and; (3) delay in division. Less well understood actions include (1) differentiations, aging and death of so-called vegetative intermitotic or stem cells; (2) effects which interfere with the action of humoral factors involved in the regeneration of certain tissues, including derivatives of the reticuloendothelial system; and (3) effects involving the cellular and noncellular immune responses of the organism.

2. Significance of different types of ionizing radiation in process: There are several important differences between lesions to be expected from penetrating radiation and from beta radiation from fallout particles. Once the beta particles have reached the surface of the earth, they contribute to the general activity of the area, but do not endanger the skin surfaces to any extent, because they penetrate only a few millimeters of tissue and almost any covering affords some protection. Overexposure to gamma rays may be followed by the acute radiation syndrome, and death or recovery in a matter of weeks, while exposure to high levels of beta radiation may result in third-degree burns requiring long hospitalization and extensive skin grafting.

In early casualties due to fallout in the general vicinity of the nuclear weapon used, one is concerned chiefly with the "recoverable component" of radiation injury. With such fallout pattern, depending on meteorological conditions downwind from the site of detonation, the terrain, weapon, point of detonation, etc., time, intensity and quality factors of irradiation become as important for prognosis, as they are in formulating a radiation prescription for the treatment of malignant disease. From a research standpoint also, the recoverable component of irradiation injury appears to be the key to survival following total body irradiation.

3. Ionization is thought to result in the breakdown products of water in the presence of oxygen into OH, H, O_2H, and H_2O_2; with the exception of hydrogen, these are powerful oxidizing agents. As to the locus of the radiation effects, in cells, two theories are advanced. One, the target theory localizes the action with some vital component of the cells. The other, the indirect theory, relates more

to the general action of the breakdown products of water. Both types of action probably account for radiation injury. One of the most important cellular effects is enzyme alteration. This generally occurs by oxidization of the SH groups or by protein denaturation. There is also a reduction of nucleic acid synthesis and arrest of mitosis. The use of the terms direct and indirect effects of irradiation should distinguish whether one is speaking of a single cell or the whole organism. Thus, ionizing radiation effects on the small bowel epithelium are direct in the sense that they are not appreciably inflamed by shielding various portions of the body other than the area of small intestine irradiated. Such effects within a single proliferating mucosal crypt cell may be both direct and indirect, although the latter, presumably mediated by the production of certain highly reactive radicals, appear to be the most important.

Various tissues of the body respond quite differently, in terms of ultimate effect, to the same cumulative dose of irradiation—total body and otherwise—fractionated in different ways. (See also data by Nachmansohn and Cotzias and Serlin under X, Bl.)

4. As a general rule, the sensitivity of a call to radiation varies as the mitotic activity and inversely as the degree of differentiation. Ranging from the most sensitive to the least sensitive, are the lymphocytes, erythroblasts germinal epithelium of tastes, myloblasts, intestinal crypt epithelium, ovarian germinal cells, basal layer of skin, connective tissue, liver, pancreas, kidney, bone, brain, nerve, and muscle. It is important to distinguish between radiosensitivity and radiocurability as well as the biological effect under consideration.

5. Effects of the whole organism.

(*a*) There is a wide difference in susceptibility of various animals to total body irradiation. The approximate LD 50/30 doses of total body radiation are as follows:

	Roentgens		*Roentgens*
Guinea pig	250	Rat	590
Dog	300–430	Mouse	500–650
Swine	420	Burro	580–780
Man	450 (estimated)	Rabbit	790–875
Monkey	500 [1]	Chicken	1,000
Sheep	520	Turtle	15,000

[1] For servival period of 67 monkeys at various gamma radiation doses see Effects of Barium^{140}–Lanthanum^{140} etc., under B.1. For recent review of the Effects of Radiation in Mammals, E. P. Cronkite and V. P. Bond, American Review of Physiology, vol. 18, 1956.

The difference in the lethal dose of total body irradiation upon various mammalian species: guinea pig, 200 roentgens, rabbits, 800 roentgens, has been directly correlated with degree of the recovery of delay in bone marrow produced in the particular species involved by such dose.

(*b*) Micro-organisms vary tremendously in their susceptibility to radiation. To destroy all bacteria in milk, for example, requires at least 750,000 roentgens. Tobacco mosaic virus requires 1,800,000 roentgens.

(1) Position of man: There are no exact data. The LD50 figure of 350 roentgens proposed from the Marshallese contrasts with a commonly quoted value of 400 roentgens or 450 roentgens. (Handbook of Atomic Weapons for Medical Officers prepared by the Armed Forces Medical Policy Council for the Army, Navy, and Air Force, June 1951), and a recent evaluation of the Japanese World War II casualty data something in figures well bove 400 to 450 roentgens for the immediate radiation from the bomb. (See Marshallese report).

6. The clinical syndrome in man of radiation injury in the sublethal and lethal range presents a fairly uniform hematopoietic pattern. In the sublethal group, there is an early and profound drop in lymphocytes with the neutrophil count showing an initial rise in 12 to 48 hours and then falling to pre-exposure level with a maximum drop from 5 to 6 weeks. Platelets start to decrease in a few weeks with a maximum low in about one month. During the first few weeks the hematocrit falls off only slightly if there is no bleeding. In the lethal ranges the same course of events occur but are markedly acceleraed and of greater intensity. The platelets drop off by the 4th day and completely disappear by the 10th. This general hematopoietic depression ties in with the subsequent bleeding and infection susceptibility. In the delayed effects the shortening of life span may result from such general factors as lowered immunity, damage to connective tissue, and premature aging. The question of specific tissue damage is indicated by the increased tendency to leukemia and skin cancer in certain exposed individuals. However, the carcinogenic factor is not too well established in humans.

For syndrome of nervous symptoms, see joint report of Hiroshima and Nagasaki casualties, etc., by Shiraki et al., under X, B,1. Also in National Academy Sciences report, 452, pages v-5–v-62.

G. Relationships of damage mechanisms to dosages

1. Production of leukemia and neoplasms (under mechanisms and response of man to radiation and radioactivity) exposure to ionizing radiation has been generally accepted as a leukemogenic factor in man (Kaplan, H. S., Cancer Research, 14, 535, 1954).

The high incidence of leukemia in radiologists, 8 to 10 times the incidence in nonradiologists has been widely accepted as evidence of this factor (Ulrich, H., New England Journal of Medicine, 234:45, 1946). Further evidence has been the cases of leukemia and malignant epithelial lesions (Hepatomas) many years after the diagnostic use of Thorium dioxide (Thorotrast).

More recent evidence is the preliminary report from England in 1956 on the apparent increased incidence of leukemias in children following exposure to weak irradiation received through prenatal diagnostic pelvimetry (Stewart, A., Webb, J., Giles, D., and Hewitt, D., Lancet 2: 447, 1956).

Aplastic anemia: It is well known that the atomic bomb victims that survived the blast and were exposed to extensive radiation died with aplastic or hypoplastic bone marrows. The sequence of the morphologic changes in the bone marrow have clearly been described by Liebow, Warren, and DeCoursey (American Journal of Pathology 25: 853, 1949). In experimental animals evaluation of bone marrow radiosensitivity indicates a variation in degree of sensitivity of the hematopoietic elements with the granulocytic and erythroid elements being most sensitive and fat cells and reticulum cells the least sensitive and even quite radioresistant (Bloom, M. A., and Bloom, W., Journal of Laboratory and Clinical Medicine, 32: 654, 1947). However, more recent studies have indicated that erythropoietic elements are definitely less sensitive than granulocytic (Valentine, W. N., and Pearce, M. L., Blood, 7: 1, 1952).

The use of repeated large whole-body irradiation exposures has been studied by Valentine, Pearce, and Lawrence in the cat using 4 exposures of 200 r over a period of 1½ years. Although the exact L. D. 50/30 days is not known, their preliminary work indicated that probably was in the 300 to 350 r range.

Nevertheless, a single dose of 200 r represented a severe hematologic insult. Recovery occurred within 30 days following each exposure with very little detectible marrow damage after four exposures. (Valentine, W. N., Pearce, M. L., and Lawrence, J. S., Blood 7: 14, 1952.)

For a population of 100 million with a lifespan like that of the United States, each absorbed roentgen of whole-body radiation would result in about 6,000 cases of leukemia during their life time, while one-tenth the "maximum permissible dose" of Sr^{90} would result in 35,000 cases. (E. B. Lewis, Leukemia and Ionizing Radiation. Science, 1957, 125 in press.)

GENETIC EFFECTS

H. The nature of genetic effects: Studies, beginning with Mendel, demonstrated that the characteristics of living things were inherited following certain specific laws. Animal-husbandry men and farmers knew most of this but could not interpret the genetics laws properly because of ignorance and lack of information concerning genes and the requirements for expression of inherited characteristics. The germ cells containing only a single set of chromosones which in turn carry only a single set of genes transmit the characteristic of one parent to the child. The child has a double set of chromosones and genes consisting of one set from each parent. Since the characteristic for one parent may be dominant over that of the other, the child will show a mixture of characteristics; some from one parent, some from the other, and some which were common to both parents. Studies with plants, insects, and animals have demonstrated the accuracy of these concepts.

Because there are so many genes and so many variations among the genes for the same characteristic, there is considerable opportunity for variation which in turn permits opportunity to meet changes in the environment. There is still another mechanism which acts as a safeguard to allow the various species to change and thus adapt themselves to severe and marked alterations in the environment. This mechanism is called mutation. It consists of an abrupt, spontaneous change in a gene, producing a change in a recognizable characteristic. Most mutations are detrimental to the species and would be of value

only if there was a considerable change in the environment. It has been estimated that approximately 1 in 10,000 germ cells will undergo such mutation.

Frequency of tangible genetic effects as given by NAS report, i. e., mental defects, epilepsy, congenital malformations, neuromuscular defects, defects in vision or hearing, cutaneous and skeletal defects, or defects in the gastrointestinal or genito-urinary tracts, make up about 4 to 5 percent of all the live births of the United States. Of these about 2 percent are genetically caused. But this is not the natural mutation rate, which also includes lethals, changes in fertility, life span, etc., which are hard to detect and other nonharmful changes (eye color, etc.). Therefore it may be as Muller suggests, more like 1 in every 5, or 20 percent.

Recognized causes for natural mutation are temperature, chemical substances (particularly azone), and radiation. Again based on experiments with insects and animals it has been estimated that radiation equivalent to 30 to 80 r, whole-body dose, will double the normal spontaneous mutation rate. Further it has been demonstrated that the time over which the radiation is received does not affect the mutation rate.

Russell's studies on mutation of seven genes in mice show that about 30 r delivered to immatured germ cells constituted the doubling dose. There is probably not much higher in man, it may even be lower.

Since man exhibits a longer life span than mice and Drosophilia, it is likely that more of the spontaneous mutations are due to background radiation. If it were equal to it (3 r) then the doubling rate would also be 3 r. It is more likely that it is about 3 times as large (10 r) as recommended by the NAS reports.

The frequency of point mutations increases linearly with radiation dosage. In Drosophilia this has been demonstrated for a range from 25 r to 6,000 r. In certain plants this is extended down to 5 r. In mice this has only been tested from 300 to 800 r. but there is no indication that it does not hold outside this range. There is no sign of a threshold below which mutations are not produced, but rather even the lowest are proportionately mutagenic, and all doses are additive or cumulate in effect.

Because gene changes are inherited and because it is very rare for genes to mutate back, the occurrence of a mutation is thereafter inherited until the end of that cell line. Consequently, the effects of mutation accumulate within the population. With random matings these genetic changes become dispersed among the population. If the mutations are detrimental they are likely to cause decreased viability and ultimately death when accumulated in the population to such an extent that both parents transmit the detrimental character to the child. In effect this eliminates the mutant from the population. Ultimately a level is reached whereby for each new mutation arising an old mutant accumulated in the population will be eliminated.

Because of these reasons it has been believed by one group of investigators led by Muller that any increase in radiation can only be harmful and ultimately will lead to degradation and degeneration of the race. However, this will require many generations before such effects could become apparent. A smaller group believes that there are certain inherent safeguards which would protect the species by decreasing mutation rate in response to radiation.

Sturtevant of the California Institute of Technology has calculated that, if the irradiation from fallout increases at its present rate, it will produce some 70 children a year carrying a mutation. This estimate he adds may be too low and, in fact 7,000 may be a better estimate. This has no noticeable impact statistically, that is, about 2 percent (150) will actually show changes from the normal. If compared to the 4 million born yearly and 40,000 defective ones at birth we need not be concerned about the effect of fallout on the future of the people at large or on mankind. Yet if the statistical approach is not used 150 individual newborn children each year will be affected.

Some of the current problems in this field are discussed in the following articles:

Crow, James F., The Estimation of Spontaneous and Radiation-Induced Mutation Rates in Man, from Eugenics Quarterly, vol. 3, page 201, 1956.

Crow, James F., Possible Consequences of an Increased Mutation Rate, from Eugenics Quarterly, in press.

Glass, H. B., The Induction of Mutations with Radiation, talk delivered at International Agency for Peaceful Application of Atomic Energy, Brookhaven National Laboratory, May 15, 1957.

Stern, Curt, Genetics in the Atomic Age, from Eugenics Quarterly, vol. 3, page 131, 1956.
Muller, H. J., Potential Hazards of Radiation, from Excerpta Medica (Amsterdam) in press.
Muller, H. J., Damage from Point Mutations in Relation to Radiation Dose and Biological Conditions, in press.

L. Concepts and definitions for standards pertaining to external radiation effects are covered in Relative Biological Efficiency of Different Ionizing Radiations, John W. Borg, National Bureau of Standards Report 2946, December 30, 1953.

M. Standards for internal radiation effects:

1. Reference is made to the report of the Subcommittee on Toxicity of Internal Emitters as given in Pathologic Effects of Atomic Radiation, National Academy of Sciences—National Research Council publication 452.

Also reference is made to the report Tentative Recommendation of the NCRP for the Maximum Permissible Levels of Radiation to Man, a copy of which is attached.

2. For methods of determining total accumulated doses and dose rates from external radiation, see Doses and Dose Rate Cures, AFSWP Manual No. 99.

N. ———.

SPECIFIC QUESTIONS FOR DISCUSSION

A. All low level effects are not extrapolations from high level effects, (for example see studies by E. Lorenz). Such extrapolations would be hazardous. However, further studies on low-level effects are particularly important since the explosion on March 1, 1954, of an experimental thermonuclear device at the United States Atomic Energy Commission Eniwetok Proving Grounds in the Marshall Islands.

B. There are quite definite distinctions between temporary and permanent (long-term) damages, and between repairable and irrepairable damage. The problem of certain long-term damages may be complicated by sequelae from effects upon tissues other than the one(s) in which the most serious lesion(s) may ultimately appear, as in the development of certain neoplasms. This has been demonstrated in the case of malignant tumors arising in the thymus following irradiation by Kaplan, and may be true also for certain other types of neoplasms arising many years after exposure, as an example, in the skin. While repairable effects are well known, the differential sensitivity of anatomical units of an apparently, morphologically, homogenous tissue may result in incomplete recovery of a sufficient number of components after high doses to result in death of the organism. Recovery of self-replenishing tissues essential to life, such as the bone marrow and small intestine (when the abdomen is the principal site of injury and after supralethal doses of total body radiation) may be sufficiently delayed until sequelae, such as those associated with panhematocytopaenia result in death even though in the case of the bone marrow recovery may still occur if such complications can be controlled.

C. * * *

D. The effects on behavior in Hiroshima and Nagasaki casualities who died during the period of 16 to 69 days is mentioned under Joint Report—Effects of Atomic Radiation on the Brain of Man, Etc., by Shiraki, et al., under X, B–1. There was little evidence of changes in mental posture, personality, and intelligence in those who died during the first 3 months after exposure. Under such conditions the dose level was great enough to cause death from anemia and other factors, but was insufficient to affect directly the brain. Japanese physicians have stated that many patients who survived the bombings have shown no neurological disabilities but have complained of generalized weakness, easy fatigability, and nervousness for years after the bombings.

E. To date we are probably limited for practical purposes in the event of mass casualities due to exposure to ionizing radiation to procedures which will (1) reduce the dose received by such things as shelter, evacuation, clothing, bathing, washing down ships of the fleet, etc.; (2) reduce and combat complications such as burns, indirect injuries from blast effects, and infection; and control the sequelae of panhematocytopaenia, and disturbances in water and electrolyte balance, by procedures in general use for such syndrones from any cause. The possibility of adding to this armamentarium by more specific therapeutic measures, including both humoral and cellular factors appears probable from research to date, but has not been consummated.

F. Unless all radiological factors are reported, and radiation procedures such as fluoroscopy standardized as far as practical, a record of the number of roentgens received by each person during his lifetime would probably not be very meaningful. For example, to record the fact that on a film badge a patient received 10 roentgens, per se, is no more informative than a statement that he was given 10 milliliters of a substance intravenously without indicating the concentration of the solution.

G. The total estimated dose rate to gonads from natural sources of radiation both internal and external is 0.095 roentgens per year. In addition it is estimated that diagnostic radiology contributes 22 percent of the above natural radiation dose. Occupational exposure in radiology and industry adds at least another 1.6 percent of the natural radiation dose. (The Hazard to Man of Nuclear and Allied Radiation, presented to the Lord President of the Council to Parliament by Command of Her Majesty, June 1956.) H. (The numbering of the questions skips from H to J).

J. * * *

K. Radioiodine acts principally on the thyroid, but a possible relationship to leukopenia and anemia has been suggested. The doses and expected effects are as follows:

(*a*) 1 or 2 milliocuries I^{131}: This is the lowest amount that will cause transient alteration of physiological activity of the thyroid. No recognizable histologic changes would be expected.

(*b*) 10 to 15 millicuries I^{131}: This amount will cause a mild transient decrease of thyroid activity, probably detectable only by laboratory tests. The depression may last a few months. Histologic alterations, if any, would be in the form of mild fibrosis and slight los of follicular epithelium.

(*c*) 35 to 75 millicuries I^{131}: Usually given in fractional doses, this total amount can be expected to produce definite clinical hypothyroid state for between 6 and 12 months. Histologically, there would be varying degrees of fibrosis and follicle destruction.

(*d*) Two courses of 35 to 75 millicuries I^{131} can be expected to produce almost complete cessation of thyroid function with severe myxedema. The duration of the myxedema cannot be predicted, as the patients tend to develop thyroid activity over the course of a few years. Histologically, one would expect virtually complete fibrosis of thyroid with a few surviving distorted epithelial cells and possibly a few distorted follicles. Eventually, some regeneration of follicles might occur. Even though there may be widespread destruction of thyroid, the parathyroids are unaffected.

(*e*) 1,200 to 1,500 millicuries: This total amount has been given over a period of several years to a few patients. Leukopenia and/or anemia has sometimes developed and been attributed to the radiation effect or circulating I^{131}, but there is no proof that the hematologic changes were due to I^{131}. Amenorrhea has been reported, but there is no proof it was the result of I^{131}.

Cs^{137}: There is no evidence so far that Cs^{137} has any unusual biological properties. It does not seem to localize in bone.

C^{14}: This is eliminated fairly rapidly (about 97 percent in 3 or 4 days) from the body, largely as CO_2. It does not localize in bone.

BIOGRAPHICAL SKETCHES OF WITNESSES WHO CONTRIBUTED TO STATEMENT BY ARMED FORCES INSTITUTE OF PATHOLOGY

ELSON BOWMAN HELWIG

Birth: March 5, 1907, Pierceton, Ind.

High school education: Warsaw Indiana High School, graduation 1925.

Preprofessional education: Purdue University, Lafayette, Ind., 1925–27.

Professional education: Indiana University Medical School, Bloomington, Indianapolis, Ind., B. S. June 1930, M. D. June 1932.

Internship: City Hospital, Indianapolis, Ind., rotating service 1932–33.

Residencies: City Hospital, Indianapolis, pathology, resident 1933–34; Institute of Pathology, Western Reserve University, Cleveland, Ohio, pathology, assistant resident 1934–35; City Hospital, Cleveland, Ohio, pathology, resident 1935–36; New England Deaconess Hospital, Boston, Mass., assistant pathologist, 1936–39.

Certified by the American Board of Pathology: 1938.

Membership in Professional Societies: College of American Pathologists, Washington Pathologic Society, American Association of Pathologists & Bacteriologists, American Society of Clinical Pathologists, American Association for Cancer Research, Massachusetts Medical Society, Baltimore-Washington Dermatological Society, American Academy of Dermatology and Syphilology, International Academy Pathology.

Teaching associations and appointments with professional schools: Indiana University School of Medicine, assistant surgeon pathology, 1933–34: Western Reserve University Medical School, demonstrator, pathology, 1934–36; Washington University School of Medicine, instructor, pathology, 1939–42; Washington University School of Medicine, assistant professor pathology, 1946–47; George Washington University School of Medicine, professorial lecturer, 1947.

Military service: Army Medical Museum, 3 months, 1942; Chief of Laboratory Service, Bruns General Hospital, 1934; Chief of Pathology Branch and executive officer, 18th Medical General Laboratory, and consultant in pathology, Pacific Ocean area, 1944–45.

Present occupation: Senior pathologist at the Armed Forces Institute of Pathology; Chief of the Division of Pathology; Chief of the Pathology Branch; Chief of Derman and gastro-intestinal pathology.

1934: B. S. in electrical engineering, Georgia Institute of Technology.

1947: Diplomate, American Board Radiology.

1952: Assoc. Fellow, American College of Radiology.

1957: M. S. in physiology, George Washington University. Member Radiation Research Society, New York Academy of Sciences, Society of Sigma Xi. One year graduate work in radiation physics under Dr. G. Gailla of the Radiological Research Laboratory, College of Physicians and Surgeons, Columbia University, N. Y., N. Y. Graduate courses in atomic and nuclear physics at Georgetown University. Professorship in clinical radiology, Medical College of Virginia, Richmond. Participated in several of the nuclear weapons tests.

Present status: Head, Radiation Technology Division, Navy Medical Research Institute, Bethesda, Md.

93299°—57—pt. 1——59

SHERWOOD M. REICHARD

Born: 1928, Easton, Pennsylvania; B. A. Lafayette College 1948; M. S. New York University Graduate School of Arts and Science 1950. Master's thesis: The relation of the adrenal cortex to phagocytosis and metabolism of thorium dioxide in the rat. Ph. D. New York University Graduate School of Arts and Science 1955. Doctorate thesis: Hypophyseal-adrenal influences upon the phagocytic activity of the reticuloendothelial system.

Teaching experience: 1950–53: Fellowship at New York University, Washington Square College, instructing in general biology, histology, comparative anatomy, and general physiology.

Research

1949–53: With Prof. Albert S. Gordon, NYU: endocrine influences upon the phagocytic incorporation of colloidal thorium by the reticuloendothelial system.

1953–55: Fellowship at Brookhaven National Laboratory under auspices of Atomic Energy Commission, with Dr. Abraham Edelmann: hypophyseal-adrenal influences and x-radiation effects on phagocytosis of radioactive gold (Au^{198}) and thorium by the RES.

1955 (May–Oct.): (Interim position): waiting for commission in Army). Research Associate, with Dr. Raymond Klein, Brookhaven: D-amino acid oxidase purification and extraction—inactivation by x-irradiation, its prevention by certain aromatic acids.

1955–present: 1/Lt, U. S. Army, Armed Forces Institute of Pathology, Dept. of Radiobiology, Washington 25, D. C., with Col. Carl F. Tessmer. Radiation activation of tyrosinase, quantitation and correlation with pathological changes in skin (C^{14} studies); tyrosinase activity in melanotic tumors; x-irradiation and phagocytosis of the RES; Reticulo-endothelial protection factors in trauma.

Publications by Sherwood M. Reichard as follows:

Papers

Reichard, S. M., and A. S. Gordon. Adrenal influences upon the distribution of injected colloidal thorium. Am. J. Physiol. 186: 63–66, 1956.

Reichard, S. M., A. Edelmann, and A. S. Gordon. Endocrine influences upon the uptake of colloidal thorium. J. Lab. Clin. Med. 48: 431–441, 1956.

Reichard, S. M., A. Edelmann, and A. S. Gordon. Adrenal and hypophyseal influences upon the uptake of radioactive gold (Au^{198}) by the reticulo-endothelial system. Endocrinology 59: 55–68, 1956.

Reichard, S. M., A. Edelmann, and A. S. Gordon. Endocrine influences upon the uptake of colloidal thorium by reticulo-endothelial organs. RES Bull. 2: 34–39, 1956.

Abstracts

Reichard, S. M., and A. S. Gordon. Influence of cortisone upon phagocytosis in the spleen. Anat. Rec. 111: 558–559, 1951.

Reichard, S. M., and A. S. Gordon. The relation of the adrenal to the distribution of injected colloidal thorium dioxide. Anat. Rec. 113: 85, 1952.

Reichard, S. M., A. Edelmann, and A. S. Gordon. Endocrine influences upon the uptake of radioctive colloidal gold (Au^{198}) by reticulo-endothelial organs. Fed. Proc. 15: 149, 1956.

Reichard, S. M., A. Edelmann, and A. S. Gordon. Endocrine influences upon the uptake of colloidal thorium by reticulo-endothelial organs. VIth International Congress of the International Society of Hematology, 279–280, 1956.

Papers in preparation

Strain differences in the phagocytosis of colloidal radiogold. Effects of X-radiation upon the uptake of colloidal radiogold by the reticulo-endothelial system.

WEBB HAYMAKER, M. D., M. SC.

Birth: June 5, 1902, Washington, D. C.

1920–22: College of Charleston, Charleston, S. C.

1922–23: Clemson College, Clemson, S. C.

1923–24 and 1925–28: Medical College of South Carolina, Charleston, S. C. (M. D.).

1924–25: University Würzburg, Germany, and University Vienna (Anatomy)

1928–29: Resident in Pathology, Pennsylvania Hospital, Eighth and Spruce Streets, Philadelphia.

1929–31: Intern (rotating), Pennsylvania Hospital, Philadelphia.

1931–32: Part time Henry Phipps Institute, Philadelphia (clinical and experimental tbc. with Opie and Freund); part time Pennsylvania Hospital, 49th and Market Streets (nuropathology with Alpers).

1932–33: Intern, American Hospital, Paris; part time Institute du Cancer, University Paris (with Roussy and Verne; tissue culture CNS).

1933–34: Director of Laboratories, State Sanatorium, Wallum Lake, R. I.

1934–35: Fellow in Neurology and Neurosurgery, Montreal Neurological Institute (with Penfield), McGill University (M. Sc.).

1935–36: Clerk, National Hospital, London (with Carmichael) and Institute de Cancer, Madrid (with Hortega).

1936–42: Assistant clinical professor neurology and lecturer in neuroanatomy, University of California, School of Medicine, San Francisco and Berkeley.

1942–47: Lt. Col., M. C., AUS, Army Institute of Pathology, Washington, D. C. (Neuropathology). July 1, 1957: Retired, U. S. Army Reserve Corps.

1947– Chief, Neuropathology Section, Armed Forces Institute of Pathology, Washington, D. C.

1946–57: Professorial Lecturer in Anatomy, George Washington University School of Medicine, Washington, D. C. (1957—Special Lecturer in Anatomy).

1950: Associate Professor of Neurology, Georgetown University School of Medicine, Washington, D. C.

Membership in honorary society: Alpha Omego Alpha (Medical College of South Carolina).

Membership in societies: American Neurological Association, American Association of Anatomists, American Association of Neuropathologists, American Association of Pathologists and Bacteriologists, American Academy of Neurology, Association of Military Surgeons of the United States, Association for Research in Nervous and Mental Disease, International Academy of Pathology, Vereinigung Deutscher Neuropathologen (corresponding member) (1950), 38th Parallel Medical Society of Korea (charter member) (1951), Washington Academy of Sciences (1951), Gesellschaft zur Erforschung des Vegetativen Systems (Vienna) (1952), Sociedade de Neurologia do Rio de Janeiro (corresponding member) (1953), Société Francaise de Neurologie (membre d'honneur a titre etranger) (1953), Academy of Medicine of Washington, D. C. (1955), American Academy of Cerebral Palsy (1956).

Offices held: President, American Association of Neuropathologists, 1955–56; vice president, IIId International Congress of Neuropathology, Brussels, July 1957.

Editorial assignments: Member, advisory board, Journal of Neuropathology and Experimental Neurology; member, editorial board, American Journal of Pathology.

Accredited by the following specialty boards: National Board of Medical Examiners, American Board of Psychiatry and Neurology, Inc. (in neurology), American Board of Pathology (in neuropathology).

Affiliations: Member, research advisory board, United Cerebral Palsy; assistant, American Board of Psychiatry and Neurology, Inc.; research collaborator, Medical Department, Brookhaven National Laboratory, Upton, Long Island, N. Y.; member, Committee on Pathologic Effects of Atomic Radiation (Chairman: Shields Warren), National Academy of Sciences—National Research Council.

Representative HOLIFIELD. Our next witness is Dr. Austin M. Brues, of the Argonne National Laboratory, director of the Biological and Medical Research Division since 1946, and delegate to the U. N. Radiation Committee.

All right, Dr. Brues.

STATEMENT OF DR. AUSTIN BRUES, DIRECTOR, BIOLOGICAL AND MEDICAL RESEARCH DIVISION, ARGONNE NATIONAL LABORATORY [1]

Dr. BRUES. Thank you, Mr. Chairman.

I do have a short prepared statement which I intend to read in its entirety.

---

Representative HOLIFIELD. All right.

Dr. BRUES. I want to speak chiefly concerning the philosophy of setting and determining the permissible levels which Dr. Taylor spoke of earlier this morning, and what the true basis of our understanding of these is.

The presently accepted safe levels of radiation and of radioisotope incorporation are based on a long history of clinical observation and experimental research. These levels have been determined on the basis of making the most pessimistic assumptions where knowledge is lacking and then introducing a factor of safety.

Where direct observations on human beings or suitable animals have been at hand, the practice has been to divide those levels which produce any detectable effects by 10 to arrive at a permissible level. It was on this basis that the permissible daily X-ray exposure of 0.2 roentgen to the whole body was reduced many years ago to 0.1 roentgen, and then, as a result of some further work which was done during the Manhattan District days, particularly having to do with the production of sperm in dogs given one-half roentgen a day, which showed dogs had some changes in the rate at which they produced a sperm, it was considered one-twentieth of a roentgen a day would be a safer dose.

The question then came up as to whether these levels had to be adhered to each day or whether one might not receive a week's dosage on Monday morning without any further effect than that incurred by spreading it through the week. While an acutely dangerous dose of radiation—say 500 roentgens—is less toxic if spread out over a week owing to the rapid recovery of the blood-forming tissues, there seemed to be good experimental evidence that the late consequences of low doses were rather independent of time, and so three-tenths of a roentgen per week was accepted. It seems quite likely that the whole yearly quota of 15 roentgens—which in itself produce no obvious effects—might as well be incurred on a single day, but three-tenths per week appears to be more practical, except for special cases such as might arise under civilian defense conditions, where a calculated risk might be acceptable.

That sort of thing has also been allowed for.

Ingestion or inhalation of radioactive substances presents a different problem. These sources of radiation may become concentrated in certain tissues and organs, and the greater part of the radiation energy, depending on type, may be given locally. The most striking example of this is the concentration of radioactive iodine in the thyroid gland, where half of the dose may be deposited in one one-thousandth of the body. We do not, unfortunately, for purposes of cancer treatment, know of any other such striking case of an extreme localization.

There have been two ways of solving this question. One has been to calculate the radiation dose in the "critical organ," that is, the organ with the highest radioactive concentration, and then to set levels of exposure such that the equivalent of three-tenths roentgen a week will not be exceeded. The other has been—and this is used where the bony tissues receive the highest dose—to compare the possible damage with that produced by radium in the human skeleton, since we have knowledge derived directly from the histories of persons who have been poisoned by radium through industrial exposure in the watch dial painting business or through administration of

radium as a drug in the days, 25 to 30 years ago, when it was thought that radium might be beneficial in certain conditions for which there was no known effective treatment.

Since no damage had been observed in patients who retained less than 1 microcurie of radium in the skeleton, about the amount in a radioactive watch, this was again divided by 10 and one-tenth microcurie was established as a permissible amount of radium. To this day, no detrimental effects have been seen in persons containing this amount of radium.

Since the preparations used to paint luminous watch dials and for some medical uses contained considerable amounts of other radioactive elements—specifically mesothorium—it has been suggested that pure radium may be less toxic than indicated here. This point is not settled, and a search is being made for other persons who may contain abnormal amounts of radium in order to improve our knowledge. In particular, it is becoming clear that a good number of persons may harbor more than 1 microcurie without detectable harm of any sort, and that the proportion who do suffer for a given amount is lower than was believed.

Since the first cases seen, and the majority, were found out because they had complaints which directed the attention of physicians to them, we see a selected group of people who met with the worst result; the well ones are much less likely to come to our attention.

This, again, I think, introduces somewhat a factor of safety in the question of how much radium is likely to produce serious effects on the human being.

These radium levels have been transferred to other radioactive materials as a result of comparing effects of radium on animals against those of plutonium or radioactive strontium. Plutonium turns out to be somewhat more toxic than would be expected from physical calculations of the radiation to bone, and this is apparently because plutonium is deposited near those cells which are active in bone growth.

Radioactive strontium 90 has been determined to be one-tenth or less as likely to produce bone tumors as radium for a given number of microcuries. On this basis, 1 microcurie of strontium 90 is considered as the equivalent of one-tenth microcurie of radium and, therefore, is designated as the maximum permissible level.

These levels were employed very successfully in the atomic-bomb project during wartime. Most of the workers remained very far below the permissible levels.

If you set up a level which is not to be exceeded, it happens, administratively, that things work out so that people get very much less.

There is the story of one individual on the project who attempted to receive his 10th roentgen per day because that is what he thought he was supposed to do. But, in general, nothing like this happened.

For practical purposes it is necessary to determine many more things than just the safe level of body content. We must also translate this into the amount which can safely exist in the air breathed and in the food and water ingested, in order to regulate these concentrations at a level which will not permit an excessive load to exist in the body. These are, then, the MPC's, or maximum permissible concentrations. This means we must use our best information as to how much is retained in the body from inhalation and from the digestive tract, and how fast it is lost from the body by excretory processes.

Many of these things have to be decided upon before the enormous amount of experimental work required for an exact answer can be carried out. There is no time here to discuss all this, but I can say that those committees shouldered with responsibility for such decisions always use the strictest possible assumptions, and, since several separate assumptions must be made—for example, how much in the air gets into the lung, how much in the lung is kept there until it gets into the circulation, how much of that is deposited, and how fast it is lost from the organ—as well as the relative effects of types of radiations from different elements, each of these considered in the worst light, we end up by multiplying a number of different factors of safety and are almost certain to come out with a level much lower than the correct one.

To give a few examples:

When tritium was first under consideration, it was noted that it has a remarkably short-range beta radiation, and nothing like it had been studied experimentally. So a factor of safety of 10 was introduced until it was shown that it acts about the same as the more familiar radiations, when this factor could be thrown out. Similarly, the strontium and radium levels were based on an early assumpion that they are lost from the bone according to a very slow process, which was measured on patients and animals a long time after its acquisition. This led to very low levels being recommended in water. It has since become known that loss occurs very rapidly at first, so that it requires about 10 times as much taken in to maintain a given level. The MPC's in this case have not yet been changed until complete study of the problem can be made, although the evidence is now fairly clear.

In another instance, a stringent level of radium in water was suggested unofficially, and we found that it was actually less than that in the drinking water of our laboratory. Had this been adopted, we would have been required to distill our own domestic supply before we could be permitted to let it flow off the grounds.

Of course, radioactive materials, as you have probably heard in the last few days, because of their special nature and the degree of development of our instrumentation, can be detected in relatively much smaller amounts than almost any other toxic material. This may be a large part of the reason for the disproportionate public concern about radioactivity relative to other noxious things.

As you are aware, there has been a general lowering of levels recently, since artifically produced radioactivity has become wider in its scope.

Here, we have to keep two things quite distinct. First is the problem of genetic effects, which will be discussed by others. The special features of these is that they seem to be produced without threshold: that is, any small amount of radiation will produce its proportion of changed genes; and that almost all of these are hidden and are perpetuated through generations till they come together accidentally through interbreeding. Thus, very stringent levels are recommended, but they do not refer to any individual but to the whole population; thus an average figure for the whole population is all that is to be looked for.

The other is concerned with the matter that we must not only consider, as was the basis of the original levels, a selected group of in-

dustrially exposed persons, but also many persons outside this group who might be close to installations where exposures could occur.

One asks, of course, why if a level is safe for one group, it is not for another. There are several reasons for this, none complete in itself. One is that the occupationally exposed group are selected, do their work voluntarily, are under medical control and are monitored. Another is that persons not in the atomic energy business may be in other fields of work which have their own peculiar hazards. Still another may be that there are more chances for an overexposure to occur. So that we might set the levels so that a considerable "overexposure," on that basis, would still not be an overexposure in the sense that it get to a level which would be within the potential danger zone. For these and other reasons, in one sense or another philosophical, we have adopted another safety factor of 10.

Mr. RAMEY. On our last point there, about your safety factor of 10 with respect to strontium 90, would the fact it applies mostly to the takeup of strontium 90 as it affects persons that it would be more as it applies to children, and therefore a lower factor when you go from an occupational group to a population group to take into account the bone-forming period?

Dr. BRUES. Well, this question has been raised. Actually I do not know of evidence that the skeleton of the child is more sensitive, except with respect to the fact that if one starts as a child and continues to an adult, he puts more of the material away. This, I think, has already been taken into consideration. We could still have more evidence on this, but data I have seen does not suggest the child at these low levels, where not stunting his growth, is going to show any more results than certain total amounts for others.

Representative HOLIFIELD. It is a fact that the bones of a child are growing and accumulating more cells at a faster rate of cell growth than the adult, is he not?

Dr. BRUES. That is true, yes; and on a given intake level, a larger total will be evident.

Another consideration which has led to extra safety is that of the fluctuating level of exposure. Where we have set conditions for exposure to external radiation we have allowed for such fluctuations. It seems equally reasonable for the level to say, radioactive strontium in water to exceed the MPC by 7 times 1 day a week; or for the point of disposal in a highly polluted river to exceed the MPC so long as it is diluted out before it reaches a point where it would conceivably be ingested—remembering also, that the MPC is based on the assumption of continuous intake for a lifetime. The same situation applies to shifting winds around a stack. For exadministrative reasons, it is therefore highly likely that conditions will be set which are much more stringent than those leading to a maximum possible concentration in personnel. It is most important to remember that that is what we are really concerned with, and that no legal culpability should be involved in an occasional fluctuation in the environment above that which would be one-tenth or one-hundredth of a dangerous level but only if it were kept up indefinitely.

The whole basis of the concept of a permissible amount, or level, by the way, rests on the assumption that there is a threshold; that is, that no harm will be done by smaller amounts. In genetics, we have reason to doubt that there is a threshold at all, so that the total popula-

tion average of exposure is set so low that it falls close to the natural variations in the natural radiation background.

Where the question is applied to other effects of radiation, such as longevity or cancer, we do not know whether they have thresholds or not. It has been suggested that they do not, but on the basis of very scanty evidence so far, and in no case is there information much below 100 r; and there are also good reasons from what we know about the nature of cancer to suspect that the hazard goes down faster than the insulating agent. An animal experiment to guarantee the existence of a human threshold below suggested off-site MPC's would be a prodigious undertaking and would drain off much of our talent from work which is really more basic to the problem. It would, moreover, detract both talent and public attention from problems of the same sort that seem, to me at least, as urgent.

For instance, millions of Americans now living will die of cancer of the lung due to something in the environment that we did not have a few decades ago. I once made a calculation by exactly the same means as are used in the calculations of MPC's, comparing lung cancer with radium cancer, and derived an MPC—occupational criteria—of 2.4 cigarettes a day. An off-site MPC would be 1 every 4 days. The only assumption made here was that cigarettes are the causative agent. If it is city smoke, this would have to be reduced in a similar proportion before the criteria used in determining permissible levels of radioactive substances would find it allowable.

Senator ANDERSON. What year would become a basis for this new item which has come into the picture? You say something about decades. How far back?

Dr. BRUES. These figures, of course, vary from place to place, and they have been coming up more slowly in the female than in the male. But in general there has been at least a tenfold increase in lung cancer since 1900, in the rates for age since 1910 up to the decade 1940–50. This is apparently still rising at a considerable rate, and, as I say, people are very much concerned about this problem.

Senator ANDERSON. Particularly with all the millions of dollars we are spending on cancer research. The more we study it, the worse it appears to get.

Dr. BRUES. This may be repeating my colleague slightly, but I will mention it again.

If we are to settle the question of threshold satisfactorily, I would say that we should carry out expanded studies on large populations of animals, but not rely on this to the extent of reducing the amount of basic work which will probably lead us sooner to a clear answer. I refer to many things, but chiefly studies on the nature and origin of cancer, the effects of radiation on cells, the nature of the aging process—for example, why a mouse lives little more than four score weeks and ten—and broad studies of medical and population statistics in relation to natural radiation.

Along with this are the whole unexplored fields within the medical and biological sciences, any one of which might turn out to be crucial to the radiation problem; recruiting and training good talent; and communication of scientific research findings.

As one who sits on various committees to discuss and, we hope, solve these problems, I am also impressed with the danger that more and

more of the best talent and time for the imaginative approach to these questions may be drawn away from the work and thought that they ought to be producing, into more and more debate over the same scanty knowledge.

May I just conclude with what might be a scientific parable, by pointing up the potential difficulties of the whole problem from an experiment done by the late Dr. Egon Lorenz.

Dr. Lorenz carried out the lowest-level experiment in chronic irradiation that has been done, giving mice a little over 0.1 roentgen daily throughout their life. He found, and thus confirmed an earlier experiment, that the irradiated mice developed more leukemias than those that were not irradiated, but that their average life span was almost 10 percent longer.

What a mouse would do in this case if he had a free choice, I am not sure.

Representative HOLIFIELD. Thank you very much, Dr. Brues, for your illuminating discussion.

Are there any questions?

Senator BRICKER. You would not want to conclude from that, if a human being was given 1 roentgen a day for his life, he would live 10 percent longer, would you, Dr. Brues?

Dr. BRUES. No, sir. Part of the parable was to say that I do not like to extrapolate animal experiments to man until they have reached a fairly good degree of ramification.

Senator BRICKER. I would not want to give him his free choice in that case.

Representative HOLIFIELD. The chart that Dr. Friedell gave in his statement showed that a lethal dose of 50 percent would apply to dogs, 350 roentgens; mice, 450 roentgens; monkeys, 500 roentgens. So that seems to be the nearest reaction as between your permissible dose of 400 roentgens to animals you are experimenting on. Is that right?

Dr. BRUES. That is right.

We do not know that the acute results run into the same proportions as late chronic effects.

Representative HOLIFIELD. There must have been some reason why they were in the same dose range, rather than rabbits, at 800, bacteria at 100,000 roentgens.

Dr. BRUES. The mammals do run, as far as acute kill goes, between perhaps 300 and 900. There is that degree of variation between the species, and this is just the amount that will kill them in a couple of weeks.

Representative HOLIFIELD. But you draw no parallel between setting the lethal dose of roentgens for man in that category?

Dr. BRUES. I would be afraid to.

Representative HOLIFIELD. Are there any further questions?

Thank you very much.

We will adjourn now until 2 o'clock, when we will have Dr. E. P. Cronkite, Dr. Edward Lewis, and Dr. Shields Warren as our witnesses this afternoon.

(Whereupon, at 12:45 p. m., the committee was recessed, to reconvene at 2 p. m., of the same day.)

AFTERNOON SESSION

Representative HOLIFIELD. The committee will be in order.

Our first witness this afternoon is Dr. Eugene Cronkite of the Brookhaven National Laboratory. He is a senior physician there.

At this time we will be glad to have your testimony, Doctor Cronkite.

I understand that your testimony will take up the subject of the effect on the Marshallese Islanders this afternoon.

STATEMENT OF DR. EUGENE P. CRONKITE, BROOKHAVEN NATIONAL LABORATORY[1]

Dr. CRONKITE. That is right, Mr. Holifield. With your permission I would like to state that due to duties I had in Nevada I was unable to properly proofread the prepared testimony and would like permission to do so later in the week.

In addition, since the subject material is rather extensive, I would like to submit for the record the official report on the Marshallese incident and also the 6-month, the 1-year, and the 2-year reports.

Representative HOLIFIELD. Without objection, they will be received and filed with the committee.

Dr. CRONKITE. In the prepared statement, I will just mention that the first nine pages go over the general problems of whole body radiation of man, and I am essentially in agreement with all that Dr. Friedell has said this morning.

I would like to make one comment in respect to the treatment of radiation injury that came up this morning. That is, that much has been learned from the experimental therapy of radiation injury in animals. It has been conclusively shown that protection can be afforded by the transplantation of bone marrow from one strain of animal to another. The protection afforded by transplantation of genetically specific material; that is, from one member of the same strain to an irradiated member of the same strain, is very good and long last-

[1] Born December 11, 1914, Los Angeles, Calif. Undergraduate studies, University of California at Los Angeles and Stanford University. A. B. Stanford University, California, 1936. M. D. Recipient Sir Henry Wellcome Prize in Military Medicine, 1949. Secretary of the Army Commendation for work, Operation Castel, 1954. Member of Phi Beta Kappa 1937; Olpha Omega Olpha 1940; Sigma Xi 1948; Fellow of the American Medical Association: American Association for the Advancement of Science Society for Experimental Biology and Medicine; American Federation of Clinical Research; International Society of Hematology; American Physiological Society; New York Academy of Science; American Society for Clinical Investigation. Resigned from the United States Navy September 30, 1954, as commander, Medical Corps, United States Navy. Presently senior physician, head of Division of Experimental Pathology, Medical Department, Brookhaven National Laboratory. Member National Research Council civil defense committee. Member of National Academy of Sciences panel to evaluate the acute and chronic effects of atomic radiation on man. Chairman of National Academy of Sciences subpanel of acute and chronic hematologic effects of atomic radiation on man. Member of Advisory Committee Atomic Bomb Casualty Commission. (Submitted by witness.)

ing. If the material for transplantation has its source in another strain of mouse, the protection is less marked or not as long lasting. If the protective material comes from another species of animal, the protection is very short lived and not nearly as effective. In principle, the transplantation of bone marrow would significantly increase the survival rate of exposed human beings to doses of radiation that would be uniformly fatal. The amounts of bone marrow needed are large, and the mongrel nature of man makes it unlikely that very much could be expected in the way of long-term protective effect. In my opinion it would be the worst type of wishful thinking to expect that one could have an effective bone-marrow bank in the case of an atomic catastrophe. Much work is yet to be done under carefully controlled clinical conditions before one could be optimistic about the use of this procedure in man under highly controlled conditions in an individual patient, let alone under conditions of a nuclear catastrophe.

With this general statement I would also like to state that certainly in human beings exposed in the midlethal dose of radiation, the clinical picture of which is very similar to that produced by depression of bone marrow due to various drugs and so on, one would expect that antibiotics and judicious use of blood transfusions would be most helpful in increasing the survival rate in the midlethal range but not in the range in which spontaneous survival is not likely at the present time.

With these general comments I would like to go to the prepared statement.

I have been asked to summarize the early effects of exposure of animals and man to external radiation with particular reference to the effects of fallout radiation on the Marshallese, the Los Alamos accident, and radium. In addition, I have been asked to comment on the beta burns in the Marshallese, and other examples of beta burns. Since my personal experience is limited to the Marshallese and animal experimentation, I shall limit myself to these and supply reference material for the others.

It is quite impossible to cover all of this material in a reasonable period of time, so I shall concentrate upon the effects of exposure to external radiation on animals and man with a clinical description of the syndrome of radiation sickness as a function of dose of radiation and highlight the discussion with illustrative material collected in the study of the Marshallese (reference 1).

My prepared statement includes numerous references and further material that time will not permit discussion of at length here.

Radiation syndromes vary as a function of the type of exposure, the dose, and the time after exposure to radiation. In general radiation injuries can be divided into three general classes:

(*a*) The syndromes of whole body radiation injury produced by penetrating ionizing radiation which are dose and time dependent.

(*b*) Superficial radiation burns produced by soft radiations—beta and low energy x or gamma radiations.

(*c*) Radiation injury produced by the deposition of radionuclides within the body.

In the latter case the clinical picture varies with the site and amount of deposition.

Each of the above is associated with an early phase in which acute symptoms and signs may be observed, and a late phase in which chronic changes or manifestations such as cancer may be observed.

I wish to emphasize also that the degree of injury and the clinical manifestations are proportionate to the dose. This is particularly true of the syndromes of whole body radiation. The latter is, and I repeat, highly dependent on dose and time after exposure. There is no simple description. The problem is subtle and complex and one must always bear dose and time in mind.

THE SYNDROMES FROM TOTAL BODY PENETRATING RADIATIONS

The dose dependent syndromes resulting from total body exposure in the mammal have been described in detail, and I shall only summarize them here. For further details one is referred to references 1 to 12.

After large doses—approximately 6,000 r or more—the central nervous system syndrome, which can be abbreviated CNS, is produced. Death may occur under the beam while being irradiated or after some hours. The clinical picture is characterized by hyperexcitability, disorders of equilibrium, incoordination, respiratory distress and intermittent stupor. Convulsions may preceed death. Doses capable of producing this syndrome are always uniformly fatal If an occasional animal, and presumably man, survives this CNS he has yet to experience the gastrointestinal syndrome (GIS), which when produced by doses in excess of 1500 r is always fatal within 3 to 9 days for mammals. Presumably man also will respond in a comparable manner as laboratory animals.

The GIS is so named because of the marked nausea, vomiting, diarrhea, and denudation of the lining of the small bowel. The GIS is a uniformly fatal syndrome in most laboratory animals. If the short duration GIS of a few hours resulting from lower doses, does not produce the 3- to 9-day death, the survivors of this syndrome have yet to experience the sequelae of bone marrow depression which has been termed the hemopoietic syndrome (HS). The HS is not necessarily fatal. It is the clinical picture that is seen in the lethal range for all mammals and in general the 50 percent lethal dose values reported, represent the LD^{50} for the sequela of hemopoietic depression—namely granulocytopenia, depressed defenses against infection, thrombopenia, and anemia with the possible resulting infections, diffuse purpurpa, and hypoxia due to anemia, any one of which may be fatal. Many detailed descriptions of the pathogenesis of these phenomena have been published (references 1–4, and 12–16).

The above picture of radiation syndromes is based on animal experimentation; however, human experience, particularly as observed at Hiroshima and Nagasaki and in the Marshallese natives has indicated that man probably corresponds quite closely to the general mammalian response outlined above with the exception of some differences in time of occurrence. The CNS apparently was not observed by the Japanese at Hiroshima and Nagasaki. One would not expect it to have been observed since doses to produce this syndrome were well within the area of almost total destruction.

The GIS with deaths in the first week are well documented clinically and pathologically as are deaths from the HS. However, in the

case of man, deaths from infection were most prevalent in the second to fourth weeks—maximum incidence during the third week—and from hemorrhagic phenomena in the third to the sixth weeks—maximum incidence in the fourth week.

In the Japanese, after the bombing of Hiroshima and Nagasaki, deaths from radiation injuries were occurring as late as the seventh week. This is in contrast to other animals where deaths from the acute phase are uncommon after the 30th day.

PROBABILITY OF SURVIVAL AS RELATED TO SYMPTOMS

Predictions of the effects of various doses of gamma radiation are essential to military and civil defense planning. If the absolute sensitivity of man to radiation were known, and if it were practical to determine the dose to groups under catastrophic conditions, a realistic statistical prognosis could be made. However, these predictions cannot be made accurately at the present time. Problems involved with estimation of dose received by the individual, present real practical difficulties. It is probable that dose estimates will be available from dosimetry devices or from dose contour lines, and the position of individuals during exposure.

The difficulties of relying heavily on the dose estimates for a single individual are apparent. The exact position of the individual and the degree of shielding will not be known precisely. The dosimetry device records the dose or dose rate, which may not reflect accurately, because of shielding and energy dependence of the device, the deposition of radiant energy at the site of interest, namely the bone marrow and the lining of the intestinal tract.

The problems associated with predicting medical effects from physical estimation of dose can be further illustrated as follows:

It is apparent that dose estimates available will be air doses. The dose received by the air is of academic interest only, since the degree of effect in living things is due to the deposition of energy and its distribution in the critical tissues. Accordingly one must know the depth dose pattern or more precisely the pattern of absorbed dose in sensitive critical tissues.

This problem has been explored experimentally at great length and is described in detail in reference 17.

More need not be said here other than the fact that the uniform field of radiation coming at an individual from all directions is more effective per *r* in air than dose of radiation of directional quality. In urban areas there may be shielding from the fallout field by buildings or inhomogeneities in the field due to drift in dry windy areas.

With the prompt radiation shielding may be significant and the proximity of large buildings may seriously influence scatter and perturb the uniformity of the radiation.

Lastly a fallout field may be made undirectional by heavy shielding from buildings on one side. Thus estimates of dose calculated from dose rates or derived from an integrating type of dosimeter that adds up to the total dose received, or from position of an individual during exposure, cannot be accepted as the best index of the probable fate of this individual, or as the final guide to treatment. The physician is interested in the individual from the standpoint of sorting casualties with some chance of survival and those for whom nothing can be done,

and of equal importance the troop commander is interested in the overall prognosis of large groups of individuals in order to make plans for disposition and replacement. These two different desires cannot be completely met by physical estimates of dose. However, nature has been helpful.

The manifestations of radiation injury vary with the amount of radiation received. In other words, the symptoms of the individual or groups of individuals becomes in a sense a personal indicator of one's own fate.

Experience with human radiation injury in Hiroshima and Nagasaki (references 4, 5, 10, and 11) with reactor accidents (references 3, 6, 9) and the fallout accident (references 1 and 18) to be described later, strongly suggest that the best index of the seriousness of exposure of the individual is the symptomatology, in addition to the physical estimate of dose.

Radiation injury is complex and subtle, and the manifestations of the injury vary considerably. In a general sense, individuals exposed in the lethal range—here some, but not all, will die in the first several weeks following exposure—can be divided according to symptoms and signs, into groups having a different prognosis. Thus they may be divided into three groups in which survival is, respectively, improbable, possible, and probable. It will be apparent that there is no sharp line of demarcation among the groups. The distinguishing features are severity and persistence of vomiting and diarrhea.

GROUP I SURVIVAL IMPROBABLE

If vomiting occurs promptly or within a few hours, and continues and is followed in rapid succession by prostration, diarrhea, anorexia and fever, the prognosis is grave: Death will almost definitely occur in 100 percent of the individuals within the first week. There is no known therapy for these people; accordingly in a catastrophe attention should be devoted principally to others for whom there is some hope or in whom therapy is clearly indicated.

GROUP II SURVIVAL POSSIBLE

Vomiting may occur early but will be of relatively short duration followed by a period of well-being. In this period of well-being marked changes are taking place in the hemopoietic tissues. Lymphocytes are profoundly depressed within hours and remain so for months. The neutrophil count is depressed to low levels, the degree and time of maximum depression depending upon the dose. Signs of infection may be seen when the total neutrophil count has reached virtually zero—7 to 9 days. The platelet count may reach very low levels after 2 weeks. External evidence of bleeding may occur within 2 to 4 weeks.

This group represents the lethal-dose range in the classical pharmacologic sense. In this group the symptom-free period—the latent period—lasts from 1 to 3 weeks, with little clinical evidence of injuries other than slight fatigue.

At the termination of the latent period, the patient may develop purpura, which is bleeding into skin, epilation oral and cutaneous lesions, infections of wounds or burns, diarrhea, or melena—black stools

from digested blood. The mortality will be significant. With therapy the survival time can be expected to be prolonged, and if sufficient time is provided for bone-marrow regeneration, the survival rate will be increased.

In group I, survival improbable, and group II, survival possible, the blood picture is not as well documented as in group III, survival probable. There are good clinical reasons to believe that in the lethal range the granulocyte depressions will be marked and below 1,000 per cubic millimeter during the second week. Observations made in Japan confirm this contention.

However, in the sublethal range it takes much longer for the granulocyte and platelet count of man to reach minimal values, as compared to other mammals. Despite the chaotic conditions that existed in Hiroshima, the data of Kikuchi and Wakisaka (reference 11) shows that there was a more rapid and marked decrease in group I, survival improbable, and group II, survival possible, than in group III, survival probable. Before going on to group III, survival probable, I cannot refrain from a comment on therapy.

Much has been learned from the experimental therapy of radiation injury in animals. It has been conclusively shown that protection can be afforded by the transplantation of bone marrow from one strain of animal to another. The protection afforded by transplantation of genetically specific material, that is from one member of the same strain to an irradiated member of the same strain, is very good and long lasting. If the material for transplantation has its source in another strain of mouse, the protection is less marked and not as long lasting. If the protective material comes from another species of animal the protection is very short lived and not nearly as effective. In principle the transplantation of bone marrow would significantly increase the survival rate of exposed human beings in the group II, survival possible, and possible to a lesser extent in the group I, survival improbable, casualties.

The amounts of bone marrow needed are large, and the mongrel nature of man makes it unlikely that very much could be expected in the way of long term protective effect. In my opinion it would be the worst type of wishful thinking to expect that one could have an effective bone-marrow bank in the case of an atomic catastrophe.

Much work is yet to be done under carefully controlled clinical conditions before one could be optimistic about the use of this procedure in man under highly controlled conditions, for an individual patient, let alone under conditions of a nuclear catastrophe.

However, the treatment of group II casualties is not at all hopeless. There is ample clinical experience in conditions where the bone marrow is severely depressed and in which there are inadequate numbers of circulating cells.

In these relatively common clinical conditions produced by sensitivity to drugs, or occurring naturally as disease processes, the combined use of the wide-spectrum antibiotics that are now available, and the judicious use of blood transfusions significantly increases the survival time of the individuals, thus giving nature a longer period of time to repair spontaneously the damage that has been suffered. Accordingly, one could feel optimistic in respect to increasing significantly the survival rate of the group II, survival possible, casualties by widespread controlled use of antibiotics. Blood transfusions would

be helpful to a limited extent for anemia. The probability of availability of enough blood for burns and other injuries is low. Hence, when blood may be needed for radiation injury, supply may be exhausted. Preparation and stockpiling for such an emergency is obviously required.

GROUP III SURVIVAL PROBABLE

This group consists of individuals who may or may not have had fleeting nausea and vomiting on the day of exposure. In this group there is no further evidence of effects of the exposure except the hematologic—blood—changes that can be detected by serial studies of the blood with particular reference to lymphocytes and platelets. The lymphocytes reach low levels early, within 48 hours, and may show little evidence of recovery for many months after exposure. The granulocytes may show some depression during the second and third week. However, considerable variation is encountered. The late fall in the granulocytes, during the sixth or seventh week, may occur and should be watched for. Platelet counts reach lowest levels on approximately the 30th day at the time when maximum bleeding was observed in Japanese who were exposed at Hiroshima and Nagasaki. This time trend in the platelet count and the development of hemorrhage is in marked contrast to that seen in laboratory animals where platelets reach their lowest levels between the 10th and 15th days and hemorrhage occurs shortly thereafter.

In this group individuals with neutrophil counts below 1,000 per cubic millimeter may be completely asymptomatic. Likewise, patients with platelet counts of 75,000 per cubic millimeters or less may show no external signs of bleeding.

It is well known that all defenses against infection are lowered, even by sublethal doses of radiation, and thus, patients with severe hematologic depression should be kept under close observation and administered appropriate therapy as indicated. There is reasonably good animal experimentation to indicate that sublethally exposed colonies of animals are more susceptible to endemic and epidemic infection.

The numbers of individuals in group III—survival probable—will be greater than in group II—survival possible—and the number in group II will be greater than in group I—survival improbable. Group I casualties will be helplessly injured. Group II casualties will be able to help in their own care to a limited extent. Group III casualties will be useful and a moderate amount of work will not be harmful. No therapy other than observation is needed for this group.

The rest of my comments will be focused on the fallout accident that occurred on March 1, 1954.

Following detonation, unexpected changes in the wind structure deposited radioactive materials on inhabited atolls and on ships of Joint Task Force 7, which was conducting the tests.

Radiation surveys of the areas revealed injurious radiation levels; therefore evacuation was ordered, and was carried out as quickly as possible with the facilities available. Although the estimated accumulated doses to human beings were believed to be below dangerous levels that would produce lasting injury or mortality, the commander of the task force requested assistance of the Department of Defense and the United States Atomic Energy Commission. A medical team was requested which would be organized to provide the best possible

care of the exposed persons and to make a medical study of the exposures. The responsibility for organization of the medical team was shared between the Armed Forces special weapons project of the Department of Defense, and the Division of Biology and Medicine of the Atomic Energy Commission.

Since speed was essential, and since the United States Navy Medical Department had experienced personnel available at the Naval Medical Research Institute and the United States Naval Radiological Defense Laboratory, the Surgeon General of the Department of the Navy was requested to provide assistance.

He promptly complied, and directed the organization of a team from the two above-mentioned laboratories. I had the privilege to be the director of this team.

Within a period of 3 days, equipment was assembled and packed, and the team was airlifted to the Marshall Islands, arriving on the eighth day after the explosion.

The interim care and study of the exposed individuals had been ably taken care of by the limited medical facilities of the United States Naval Station, Kwajalein. I am pleased to call attention to the fact of the very high degree of cooperation between all Government agencies concerned and to the numerous individuals who selflessly gave of their time and efforts. The number is large, and due credit and acknowledgments are given in the official report of the incidence published by the United States Government Printing Office, and listed in reference 1.

NATURE OF THE EVENT AND DESCRIPTION OF THE EXPOSED GROUPS

The radioactive material fell on the inhabited atolls of Rongelap, the heaviest dose; on Ailinginae; on Rongerik where American servicemen were stationed, and Utirik where the smallest dose was received, but by the largest number of people. The Marshallese were living under relatively primitive conditions in lightly constructed palm houses.

The American military personnel had the second highest exposure. They were more aware of the significance of the fallout than where the Marshallese, and promptly put on additional clothing to protect their skin. As far as duties would permit, they remained inside of aluminum buildings. In contrast to this the Marshallese in general remained outside, and accordingly were more heavily contaminated by the material falling upon the atoll and upon them.

All of the exposed human beings were evacuated by air and surface transportation to the United States naval station, Kwajalein, as promptly as facilities would permit. Since a survey of the individuals showed that there was significant contamination of the skin, clothes, and hair, the clothes were removed and laundered and repeated washings of the skin and hair were carried out with fresh water and soap. The hair of the Marshallese was decontaminated with difficulty because of the heavy coconut-oil hair dressing they used.

On Rongelap there were 64 individuals that received an estimated dose of 175 r. On Airlinginae there were 18 individuals receiving approximately 69 r. On Rongerik there were 28 American servicemen receiving approximately 78 r. on Utirik there were 157 individuals receiving approximately 14 r.

Senator ANDERSON. Where do you get those figures, Doctor?

Dr. CRONKITE. I will come to that in the next section. I will discuss how the doses were arrived at.

Senator ANDERSON. We heard it suggested this morning that lots of figures are not too reliable. I am wondering if you had a way of measuring this so you could be fairly sure of these figures.

Dr. CRONKITE. I will come to this in the next section and discuss the reliability of the dose estimates and the various variables that go into it.

Senator ANDERSON. Thank you.

WHOLE BODY GAMMA DOSES

Dr. CRONKITE. The determination of the whole body gamma doses are dependent upon the surveys that were made with calibrated instruments approximately 3 feet above the ground several days after the inhabitants were evacuated. In addition certain assumptions had to be made about the arrival time of the cloud and the rate of fallout of the material. Only on Rongerik where there was a recording dosimeter is arrival time known precisely. The dose rate of the continuing fallout of material was in part neutralized by the progressive radioactive decay. In addition the transit dose from the cloud passing over the atolls could not be estimated. All of these variables were taken into account and the doses calculated. These doses were consistent with the doses that were actually measured on Rongerik by film that was stored in refrigerators and by film exposed outside on this atoll.

In view of this internal consistency it is believed that the dose of calculated radiation on the atolls is reasonably accurate. Details of the calculation of the dose are in the official report which discusses in detail the probable range in values (reference 1, ch. 1).

CHARACTERISTICS OF THE GAMMA RADIATION

The fallout material when deposited on the ground formed a large planar source of radiation. The energy distribution of the radiation reaching an exposed individual is influenced by its passage through the intervening air. A knowledge of the inherent gamma spectrum as it eminates from the material itself is essential in order to determine the spectrum that impinges upon exposed individuals.

When one takes into account the spectometric data on the mixed fission products and the degredation by Compton scattering along the path in air, a dose energy histogram can be constructed, showing that there are roughly 3 regions with maxima at 100, 700, and 1500 Kev. The total exposure is thus the resultant effect of partial doses from each energy region, making the exposure energy condition significantly different from those of radiation therapy, experimental biology, or from the prompt gamma radiation of the bomb.

Details of the characteristics of the exposure are discussed in reference (reference 1, ch. 1).

Actually the overall effect of the geometry and spectrum is to produce a very uniform deposition of energy throughout the body so that per roentgen in air fallout radiation is relatively more effective than the prompt radiation from the bomb or the radiation from an X-ray tube.

THE CHARACTERISTICS OF THE FALLOUT MATERIAL

The fallout material consisted predominantly of flakes of calcium oxide resulting from the incineration of the coral. Upon the flakes of calcium oxide fission products were deposited. At Rongelap Atoll the material was visible and described as snowlike. It stuck to the skin, adhered to the air and clothes, the vegetation, and the habitations.

Senator ANDERSON. That is what they talked about with respect to the Japanese who were in the fishing boat.

Dr. CRONKITE. Yes, sir.

Senator ANDERSON. They had this white fallout that they thought was some sort of manifestation from heaven and would not wash off for a while, and suffered as a consequence. You are describing the same sort of thing that happened down there.

Dr. CRONKITE. They were in approximately the same or a comparable position as the Rongelap natives and experienced very closely the same thing, except in their case working with their fishlines, and so on, grinding the material into their hands, they got worse skin burns than the Marshallese.

Senator ANDERSON. Thank you.

GEOMETRY OF THE EXPOSURE

Dr. CRONKITE. Time does not permit a discussion of the effect of this, but it has been alluded to earlier and details of the influence of geometry of the exposure to biologic effect are in references 1 and 17.

SUPERFICIAL DOSES OF RADIATION FROM BETA AND SOFT GAMMA RADIATION

There is no doubt that the dose of radiation to the first few millimeters of the skin is substantially higher than that at the midline of the body from the more penetrating gamma component. Problems concerned with the estimation of the dose of radiation to the skin are discussed in detail in reference 1, chapter 1.

To arrive at some physical estimate of the skin dose, an attempt must be made to add up the contributions of the penetrating gamma, the less penetrating gamma, the beta bath to which the individuals were exposed from the relatively uniform deposition of fission products in the environment and the point contact source of material deposited on the skin. By all means the largest component of skin irradiation resulted from the spotty local deposits of fallout material on exposed surfaces of the body.

To put it in reverse, the individuals who remained inside had no skin burn. It was only on those on whom the material was directly deposited on the skin that received burns.

It is completely impossible to estimate the dose from material that was deposited on the skin. The relative hazard of the beta path is discussed in detail in the previously mentioned reference 1.

CLINICAL OBSERVATIONS AND TREATMENT: SYMPTOMS AND SIGNS RELATED TO RADIATION INJURY

Itching and burning of the skin occurred in 28 percent of the people on Rongelap, 20 percent of the group on Ailinginae, and 5 percent of

the Americans. There were no symptoms referable to the skin in the individuals on Utirik. In addition to the itching of the skin there was burning of the eyes and lacrimation in people on Rongelap and Ailinginae. It is probable that these initial skin symptoms were due to irradiation since all individuals who experienced the initial symptoms later developed unquestioned radiation-induced skin lesions that will be described in detail later. It is is possible however, that the intensely alkaline nature of the calcium oxide when dissolved in perspiration might have contributed to the initial symptoms.

About two-thirds of the Rongelap group were nauseated during the first 2 days, and one-tenth vomited and had diarrhea. One person in the Ailinginae group was nauseated. No one in the Rongerik or Utirik group, or Americans, had gastrointestinal symptoms.

CLINICAL OBSERVATIONS AND LEUKOCYTE COUNTS

Between the 33d and 43d post exposure day, 10 percent of the individuals from Roneglap had an absolute granulocyte level of 1,000 per cubic millimeter or less. The lowest count during this period was 700 per cubic millimeter.

Representative HOLIFIELD. How does that compare with the normal?

Dr. CRONKITE. The normal count would be approximately 5,000 to 6,000 in American population. They were very seriously depressed at this time.

Representative HOLIFIELD. This was with an average of around what?

Dr. CRONKITE. 175 roentgens. I am sorry I did not mention it earlier. I am limiting my comments to the highest dose group. The time sequence of events in the other groups was similar but just to a less extent more or less proportionate to the decrease in dose received.

During this interval the advisability of prophylactic administration of antibiotics was seriously considered. However, prophylactic administration of antibiotics was not instituted for the following reasons:

(1) All individuals were under continuous medical observation so that infection, if it developed, would have been discovered in its earlier stages.

(2) Premature administration of antibiotics might have obscured medical indications for treatment, and might also have led to the development of drum resistant organisms in individuals with lowered resistance to bacterial infection.

(3) There was no accurate knowledge of the number of granulocytes requires by man to prevent infection with this type of granuloctyopenia as occurred in the Marshallese.

The observed situation was not strictly comparable to agranulocytosis with an aplastic marrow as seen following known lethal doses of radiation. In the latter instant, granulocytes fall rapidly with practically none in the circulation and no evidence of granulocyte regeneration when infection occurs. In the present group of individuals exposed to radiation, most counts reached approximately one-fourth the normal value, but the fall to that level was gradual and the presence of immature granulocytes in the peripheral blood during the period of granulocytopenia was indicative of some new granulocyte production. In other words, the bone marrow had not been completely eradicated by the dose of radiation received.

The few individuals that received antibiotics had conditions that would have been treated with antibiotics in the absence of any previous exposure to irradiation. During the fourth and fifth exposure weeks an epidemic of upper respiratory infection occurred. The respiratory infection consisted of moderate malaise, pharyngitis with prominent lymphoid follicles, fever during the first day, and a purulent nasal and tracheal discharge for about 10 days.

It was of interest to determine whether this respiratory infection could be correlated with the dose of radiation received or changes in the leukocyte count. There was no correlation. The respiratory infection in the medical personnel involved in the care and study of the irradiated individuals was similar in incidence and severity.

Earlier today Doctor Friedell commented upon platelets, and these were followed very carefully in the Marshallese.

CLINICAL OBSERVATIONS AND PLATELET COUNTS

Eleven individuals had platelet counts that fell as low as 35,000 to 65,000/mm.^{3}. All individuals with platelet counts less than 100,000 per mm.^{3} were examined daily for evidence of hemorrhage into the skin, mucous membranes and retina. Urine was examined daily for red cells and albumin. Women were questioned concerning excessive menstruation. The only evidence for any undue bleeding were two women who menstruated profusely at the time of their maximum platelet depression. It was not sufficient to cause them undue concern and subsided without any specific treatment.

THE EFFECTS ON PREGNANCY

Four women in the Rongelap group were pregnant when brought to Kwajalein. Two were in the first trimester, one in the second trimester and one in the third trimester. There were no abnormal symptoms referable to pregnancy. As far as could be determined the pregnancy continued in the normal fashion.

In the Ailinginae group of 69 r, one woman was in the second trimester. Fetal movements were unaffected in the individual in the third trimester. The pregnant women had a marked depression of platelet counts but at no time was there any vaginal bleeding. At the 12-month reexamination of the above women, all had delivered. One baby was born dead; the others were normal.

In the case of the one stillborn, irradiation occurred to the mother either before conception or early in the first trimester. It is possible that the irradiation may have contributed but there is no way to prove this.

SPECIAL EXAMINATION OF EYES

At all followup examinations an ophthalomogist has examined the eyes of all individuals. To date no lesions ascribable to ionizing radiation have been found. Similar studies have been made on the eyes of nonexposed Marshallese and the incidence of eye lesions is identical in the two groups.

SKIN LESIONS AND EPILATION

As mentioned earlier there was burning of the skin. On first examination by the medical team on the ninth post exposure day the ex-

posed people appeared to be in good health and the skin was definitely normal in external appearance. Evidence for the development of skin lesions commenced approximately 2 weeks after exposure.

During the early stages of development of the lesions, itching, burning and slight pain were experienced with the more superficial lesions. With deeper lesions the pain was more severe. The deeper foot lesions were the most painful and caused some of the people to walk on their heels for several days during the acute stages. Some of the more severe lesions of the neck and axillae were painful. There were no constitutional symptoms associated with the skin lesions.

The characteristic sequence of events in the development of the lesions was the occurrence of symptoms, then of black pigmented areas, small in size, which grew larger in size and coalesced. Later the skin began to shed from the inside of the pigmented plaques to the outside, and in some cases resulted in the production of large depigmented areas. In most of the lesions the shedding was limited to the superficial layers of the skin. In some the process continued with the development of superficial ulcers. A few became infected.

The appearance of these skin burns can best be illustrated by referred to chapter III of reference 1 where Kodachrome pictures illustrate the sequence of events.

In addition to the skin burns, loss of hair, spotty in nature, occurred in some of the individuals. The hair grew in again with normal color and texture and the regrowth was complete in all except possibly one middle-aged man in whom it came in somewhat sparsely. Small pieces of skin were removed surgically from some of the burned areas for microscopic study. These pieces of skin demonstrate the typical findings of radiation injury. Some of the skin burns became infected, particularly those on the feet, and were treated locally by cleansing and applications of antibiotic ointments. The skin burns healed in most cases with return of normal color and texture of the skin, and in some cases scars were left with depigmented areas.

The worst burn occurred on the back of the ear of a middle aged man. It produced a permanent scar with absence of pigment and abnormal blood vessels and a slight horny growth of the overlying skin has developed. The skin has been carefully observed at 6 months, 12 months, 2 years, and 3 years after exposure, and there is no evidence at the present time of any breakdown in the early burns of the skin. There is no evidence of the development of cancer at this time. In some the depigmented scars are still evident. The individuals have been seen on two occasions by a plastic surgeon, Dr. Bradford Cannon, of the Harvard Medical School, who feels that no plastic repair is necessary and that the prognosis in general is good.

FACTORS INFLUENCING SEVERITY OF THE LESIONS

Certain lessons were learned from the Marshallese experience.

Burns were caused by direct contact of the radioactive material with the skin. The perspiration as common in the tropics, the delay in decontamination and the difficulties in decontamination certainly favored the development of the skin burns. Those individuals who remained indoors or under trees during the fallout developed less severe skin burns. The children who went wading in the ocean devel-

oped fewer lesions of the feet and most of the Americans who were more aware of the dangers of the fallout, took shelter in aluminum buildings and bathed and changed clothes. Consequently they developed only very mild beta burns.

Lastly, a single layer of cotton material offered almost complete protection, as was demonstrated by the fact that skin burns developed almost entirely on the exposed parts of the body.

The prognosis of beta skin burns and radiation burns of the skin is excellently described in chapter III of reference 1.

HEMATOLOGIC OBSERVATIONS

It is generally considered that changes in the blood are the most sensitive biologic indexes of exposure of living human beings to radiation. Accordingly extensive simple hematologic studies were performed on the Marshallese. Since there were no previous hematologic studies on the exposed Marshallese, it was necessary to set up control groups of nonexposed Marshallese of the same age and sex distribution for comparative purposes.

I shall restrict my comments to the findings in the group from Rongelap since the temporal sequence of events are identical in all of the exposed groups. Of course the depression was less marked in the less severely exposed groups.

NEUTROPHILE COUNT

The absolute neutrophile count of both the younger and older age groups fell during the second week to a value approximating 70 to 80 percent of that of the controls. Following the depression there was an oscillation roughly around the control value until about the 30th postexposure day at which time there was a progressive decrease in the blood count with minimum values being attained around the 45th day after exposure. It is of interest that the depression in the children less than 5 years of age was greater than in the individuals who were greater than 5 years of age.

Following this maximal depression there was a slow return of the neutrophile counts toward normal. However, at 6 months they were still depressed. At 1 year and 2 years the neutrophile counts were back to the control level. However, at 3 years there was a drop in the absolute mean neutrophile count but this also occurred in the control population. It is not known whether lower counts represent a population trend as has been noted in the Japanese for both irradiated and nonirradiated populations, or whether it is merely a statistical fluctuation that is to be expected in this type of study. More work is necessary on this point.

LYMPHOCYTE COUNT

By 3 days the lymphocytes dropped to 50 percent of the controls. The percent drop in the children less than 5 years of age was greater than that of the people older than 5 years. The lymphocyte count remained at approximately the same level through the exposure period. At 6 months, 12 months, 2 years, and 3 years, the level, though increasing, had not quite reached that of the control population.

PLATELETS

The maximum depression in platelets was obtained approximately 28 to 30 days after exposure in contrast to laboratory animals that attain their minimum values between the 10th and 15th days after exposure. In this case the children under 10 years of age had a greater percentage drop than those who were older. The platelets began to recover after the 30th day, attain a maximum about the 45th day.

There was then a secondary drop with a leveling off for the remainder of the postexposure period, and at 6 months, 12 months, 2 years, and 3 years, slow recovery was still underway. The levels of the population were approaching the controls but have not yet reached it.

In all of the hematologic studies mentioned above, it is stated that the present levels are not equal to that of the control population. However, I wish to emphasize that the current levels of the blood cells of all types is more than adequate to take care of the infections and the various troubles of everyday existence. This statistical expression of an inadequate recovery probably represents the residual radiation injury that is of considerable interest to study but does not appear to be overtly harmful to the individuals. One can be reasonably confident in this because they are not faring less well in resistance to disease than are the Marshallese who were nonexposed and living in the same area.

INTERNAL ABSORPTION OF RADIONUCLIDES

During the 2 days before evacuation, the Rongelap people lived under conditions of extreme contamination without any concerted efforts to protect themselves against the dangers of internal contamination. These individuals drank contaminated water, and ate their natural foodstuffs which were contaminated externally. Their hands were contaminated; they inhaled and obviously ingested certain indeterminate amounts of material.

The body burdens of isotopes in these individuals was evaluated by radiochemical analysis of the urine of the exposed people and assisted by studies on swine. These swine were removed from the island at a later date. The urinary and fecal excretion was studied and ultimately the animals were killed. Extensive radiochemical analyses were made of their entire bodies. By comparison, approximations of body burdens of radionuclides was made. From a combination of urinary excretion and animal studies estimates were made of the probable body burden.

Rare and alkaline earths accounted for about 70 percent of the urine activity. Strontium 89 was about at the maximum permissible level at 1 day. Iodine 131 and other members of the iodine family which had to be present early, resulted in a dose of radiation to the thyroid glands, estimated between 100 and 150 rep. To this of course, must be added the penetrating external gamma component. By 6 months radiation was barely detectable in the urine. At 2 years from analysis of pooled urine samples and individual samples, very tiny amounts of strontium 90, calcium 45, praseodymium and cesium were present. Studies were performed both at United States Naval Radiological Defense Laboratory, and Walter Reed Army Medical Center.

The results of the 3-year radiochemical analysis of the urines that were recently collected are not completed as yet.

It was believed that the body burdens of these people was very low and probably biologically insignificant. However it was decided to bring some of the individuals to the United States for study with the total body gamma counter at the Argonne National Laboratory. This decision was made not because of any fear but because the analysis of the urine and the animal analysis were an indirect means to obtain probable body burdens.

It was obviously desirable to obtain a firm direct measurement of the body burden from the scientific standpoint and to determine the precise body burdens. Four individuals from the Rongelap group, 2 from the Utirik group, and 1 control Marshallese—a total of 7—were brought to the United States and taken to the Argonne National Laboratory. There, under the direction of Doctors Marinelli, Rose, and Miller, the total body gamma activity was measured. The results are yet incomplete and have to be analyzed further. It was found that the exposed Marshallese had counts that were higher than nonexposed peoples in the United States. However, the values were far below the current permissible levels.

Since there has been some misunderstanding in the press about children being brought to the United States for study, I would like to state that all the individuals brought to the United States were adults, with the exception of one 16-year-old boy. They have subsequently been returned to the Marshall Islands.

THE CONTINUING STUDY OF THE MARSHALLESE

My associate in the Medical Department of Brookhaven National Laboratory, Dr. Robert A. Conard, a member of the original team that took care of and studied the Marshallese, and director of the 2- and 3-year surveys, has retained an abiding interest in the Marshallese. On behalf of the Atomic Energy Commission and Brookhaven National Laboratory, he has undertaken the continuing responsibility of yearly surveys of these people. These surveys are being made possible by the cooperation of the Medical Department of the United States Navy and its activities, the Medical Research Institute at Bethesda, Md., and the United States Naval Radiological Defense Laboratory in San Francisco. The continuing project is a joint effort directed by Dr. Conard and participated in by the Medical Department of Brookhaven National Laboratory, the two Navy institutions mentioned earlier, and interested physicians and scientists of various American universities and medical schools. The probabilities of getting a good scientific followup are excellent.

One cannot leave this tremendously important subject of fallout and the unfortunate accident that occurred in the Marshall Islands in 1954 without the frank recognition that late effects of ionizing radiation are possible. Many late effects have been observed in man and in animals. These are condensed in detail in the National Academy of Sciences report (reference 8). Accordingly, a search for late effects is an essential part of the continuing survey.

A summary of the 3-year status of these people, which will be reported in detail in reference 22, now being prepared, follows:

FERTILITY

Effect of radiation exposure on fertility is difficult to assess in the Marshallese. If there has been any effect on fertility, it must have been very short lived, since pregnancies are occurring normally and at rates similar to other groups of Marshallese.

PREGNANCY

There has been no apparent effect of radiation on the course of pregnancy in the Marshallese. Since the delivery of the 4 women who were pregnant at the time of the event, there have been 12 pregnancies which have terminated. Ten of these terminated normally, one terminated in a stillbirth, and one baby died several hours after birth, apparently of an infection of the cord. The lack of vital statistics makes this data difficult to interpret. However, it does not appear that this incidence of stillbirths is greater than that of other comparable native groups in the mid-Pacific area.

EFFECTS ON THE FETUS

The three babies irradiated in utero have not shown any abnormalities such as was observed in some of the Japanese babies irradiated in utero. For example, microcephaly.

GROWTH AND DEVELOPMENT

On each resurvey the expcsed and control children have been matched for age and sex. Measurements on growth and development have been carried out. Anthropometric measurements have been incompletely analyzed as yet. Since the numbers of children are small, the data is not easily subjected to statistical analysis. There were 17 children less than 7 years of age and 24 less than 16 years of age at the time of exposure. However, there does appear to be a statistical evidence suggestive of a slight impairment of growth and development as measured by comparison of height and weight in the control and exposed children. You cannot look at these children and pick out any abnormalities.

I would like to comment on this rather emphatically, because of the headlines that I saw a few minutes ago. There is no gross stunting of the growth. It can only be detected by a careful statistical analysis of the data, by taking measurements of weight and height.

SHORTENING OF LIFE SPAN

In animals, the evidence for shortening of life span is quite good. It is evidence that the life shortening is some function of the dose of radiation. However, the extrapolation from mice to man is extremely difficult. It is unlikely that any good statistical analysis can be made on the Marshallese because of the small numbers of individuals and the uncertainty of the precise birth date in the older groups, prior to the American occupation in 1944.

There has been one death in the Rongelap group who, at autopsy, showed evidence of heart disease. In the larger group from Utirik there have been five deaths. The number of deaths is comparable in both groups, one having received 175 r. and the latter only 14 r. To date, one must conclude that there has been no significant evidence for premature aging or shortening of the life span of the Marshallese.

LEUKEMIA AND CANCER

Leukemia is one of the things that is known to have occurred in the Japanese and is prevalent in irradiated laboratory animals. To date, no leukemia has occurred and there is no evidence of leukemic tendencies. This is being studied intensively by the use of alkaline phosphatase studies on the granulocytes and basophile counts on the blood. It has been shown by the studies of Moloney et al. in Japan that a basophilia and decrease in alkaline phosphatase precedes the development of leukemia. They picked up a precursor tendency that is detectable prior to the frank morphological picture of general leukemia.

Genetic effects, I think, I will defer comment on, since I am not a geneticist. The number is small, and I see little chance of detecting anything of note in the Marshallese.

Representative Holifield. Is it not true that, if the male and female are married to a group that have been irradiated, there is a much greater chance of the genes being effected than if one irradiated person and a nonirradiated person were married?

Dr. Cronkite. Yes; I am sure the probability of detecting is greater by consanguineous marriage than by nonconsanguineous. I am sure this is a subject that Dr. Russell will go into in considerable detail, and I will have to confess relative ignorance on the subject.

LONG-TERM EFFECTS OF INTERNALLY DEPOSITED RADIONUCLIDES

The very small amounts of radioactive materials that are deposited internally are, by themselves, inadequate to produce serious, long-term effects. However, the subject is complicated by the fact that the individuals had a substantial initial insult from whole-body radiation. In addition to the whole-body radiation, the thyroid gland received approximately 100 to 150 r. e. p. from the short-lived iodine family. It has been reported that irradiation of the thyroid area in early life increases the incidence of cancer of the thyroid. Accordingly, thyroid function and the possibility of thyroid cancer is being studied in the Marshallese children. To date, there is no evidence of abnormality.

Before concluding, I cannot refrain from expressing my personal opinion and conviction on two aspects of the fallout problem.

First, the acute and long-term hazards of fallout, such as would occur following the use of thermonuclear devices in warfare, are simply unthinkable. The widespread contamination over continental areas from multiple detonations of thermonuclear devices over populated areas would produce radiation hazards for all living things and for generations to come. These hazards are rather well understood. These hazards cannot be considered on the usual calculated risk basis of warfare in the past. One can only make a plea that an enlightened world will demand that their representatives in government also appreciate these hazards and with this recognition bring every conceivable

effort of diplomacy to solve the problems posed by differences in political and economic ideologies and thus prevent a type of warfare that cannot be considered in terms of calculated risk.

Second, the worldwide, low-level radiation of today from diverse sources has been analyzed thoughtfully by competent people, individually and in assembly. Note the sober and realistic reports of the National Academy of Sciences, the British Medical Research Council, and the United Nations. These reports point out the multiple sources of radiation in our lives today and the necessity for continuous scrutiny. Let us not confuse unavoidable radiation exposure with radiation hazard. Let us not lose sight of the multiple sources by undue preoccupation with worldwide fallout. Let us not be so preoccupied with radiation in general that we forget about industrial pollution of our environment in general by nonradioactive but toxic substances.

Lastly, the incidence of leukemia was apparently increasing prior to the development of atomic energy. Why?

Representative HOLIFIELD. Thank you very much, Dr. Cronkite, for that fine presentation.

Representative HOLIFIELD. I think the committee is conscious of your deep feeling on the fact that regardless of how this testimony comes out in relation to the dangers of bomb testing at the rate they have been made, that there is a tremendous concern as to war with nuclear weapons. If the consensus of scientific opinion is that there has been no appreciable damage in testing at the rate we have had it to date, it is certainly not to be taken that there is any less danger from a full-scale nuclear type of attack in war.

Are there any questions of Dr. Cronkite?

Representative COLE. Yes, Mr. Chairman, I would like to ask 1 or 2.

Doctor, for my edification, would you indicate the difference, if any, and the biological consequences in the exposure to cosmic radiation as against fission radiation?

Dr. CRONKITE. I do not think there would be any qualitative difference. I think it is purely a matter of quantity. The cosmic radiation is low, if it were possible to increase the cosmic radiation the effects to be expected would be the same as with any source of radiation—external penetrating radiation.

Representative COLE. Then it is your understanding that the result and effect on the anatomy would be the same, whether from cosmic radiation or induced or artificial or fission radiation?

Dr. CRONKITE. I believe so, Mr. Cole.

Representative COLE. From what you know of the observations that have been made as a result of the studies of the Japanese population, who are exposed to radiation from the weapons fission, did those lessons vary in any degree with the lessons and observations that have resulted from the Marshallese people who were exposed?

Dr. CRONKITE. The only significant difference in the response is the Japanese were not exposed to fission products deposited in their environment but to the initial radiation from the bomb and accordingly did not have any skin burns resulting from radiation. Their skin burns were thermal in origin.

I would say that there is remarkable correspondence.

Representative COLE. I am referring to the Hiroshima and Nagasaki people; not the fishermen.

Dr. CRONKITE. I was referring to the Hiroshima and Nagasaki group. At Hiroshima and Nagasaki they were exposed to initial gamma radiation from the bomb. The fission products were not deposited on the ground. So that the Japanese there did not receive any skin burns due to contacting material. In this respect the Marshallese differ from the Japanese because they had a mixture of the radiation injury produced by the penetrating component of the gamma rays from the fission products and by the direct contact of the material on the skin with the resulting beta burns.

Representative COLE. You concluded your very fine statement with a rather imponderable question, and I am going to ask you to suggest possible answers to the question which you have raised.

Dr. CRONKITE. I think there are many possible answers. It has been abundantly proved for example that benzol and various other industrial poisons are also capable of inducing leukemia in experimental animals and presumably also man. If my memory does not fail me, and I could document this, in the lithographing industry at one time there were a few cases of leukemia presumably induced by overexposure to benzol. Certainly, many of the things that are used in medicine, where a calculated risk is deliberately taken, for the immediate welfare of a patient, occasionally one gets into trouble with drugs.

There are many things I could think of. The heavy metals. There are numerous things in the industrial life of today that can be toxic and can produce the same things that radiation does.

Representative COLE. I was impressed by an observation made by a witness this morning which, as I recall, was to the effect that since toxicity from radiation is a condition that is readily detectable by reason of our devices, that there might be an inclination to attribute the biological damage to that toxicity which is identifiable, rather than to another toxicity which might exist but which could not be so readily identified.

Do you subscribe to that general observation?

Dr. CRONKITE. I certainly do, Mr. Cole. I think you have expressed it better than I can.

Senator BRICKER. Mr. Chairman, I have just one question.

What is the ratio of body exposure to radiation from the cosmic rays and from the background material from the earth radiation?

Dr. CRONKITE. I am sorry, I did not follow you.

Senator BRICKER. The ratio that the human body is exposed to from the cosmic rays coming from the atmosphere and that radiation to which we are exposed from the materials of the earth.

Dr. CRONKITE. I am fairly confident that it is larger from cosmic radiation than from the earth, but I would have to defer to somebody who has personally investigated this field, which I have not done.

Representative HOLIFIELD. Thank you very much, Doctor Cronkite.

Our next witness is Dr. Edward Lewis. He is a professor of biology at the California Institute of Technology, and his present work is on the nature of the gene and mutational processes. He has a notable scientific background, and we will be glad to hear from Dr. Lewis at this time.

STATEMENT OF DR. EDWARD LEWIS, CALIFORNIA INSTITUTE OF TECHNOLOGY [1]

Dr. LEWIS. Mr. Chairman, with your permission I would like to use the podium.

Representative HOLIFIELD. You may proceed.

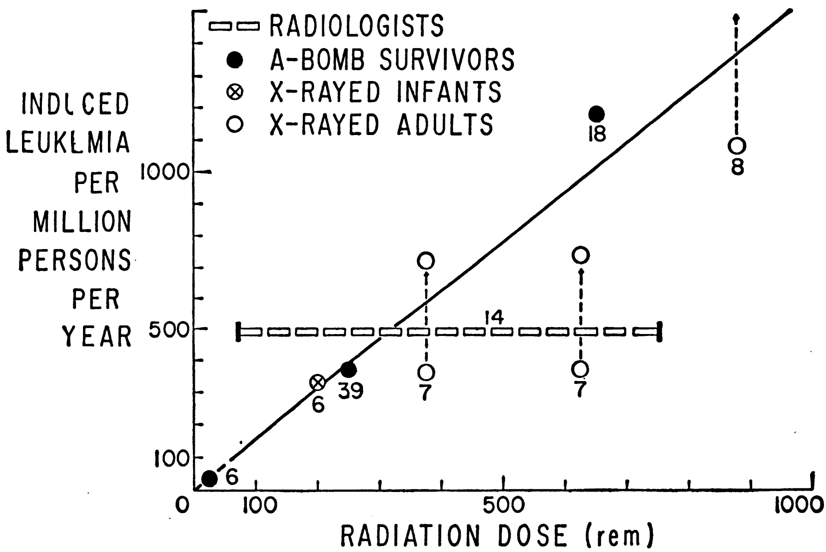
Dr. LEWIS. Mr. Chairman, I would like to thank you for this opportunity to testify. I will confine my remarks to the subject of

[1] Date and place of birth: May 20, 1918, Wilkes-Barre, Pa. Education: B. A., University of Minnesota, 1939; Ph. D., California Institute of Technology, 1942. Captain in USAF, 1942–46 (specialty—meteorology and oceanography). Fellow of Rockefeller Foundation, 1948–49; Cambridge, England. Present position; Professor of biology, California Institute of Technology, Pasadena, Calif. Present work: Nature of the gene and of the mutation process. Member of the Genetics Society of America and the American Society of Naturalists. (Submitted by witness.)

leukemia. I have been asked to do this, and I want to point out that in doing so I do not wish to imply that I think that leukemia is the most important effect of radiation on man. I think in fact possibly the genetic effects may be more important. There may also be other malignant diseases that are more important than leukemia with respect to ionizing radiation.

However, the reason that I am stressing leukemia today is that we have rather good data and rather good evidence on leukemia as compared to data on other effects on man from ionizing radiation and it is this evidence I would like to go into today.

I would like to present this evidence by means of this chart. A detailed account of this evidence has been recently published in Science (vol. 125, pp. 965–972).



Summary of incidences of induced leukemia among various groups of persons subjected to ionizing radiations. The numbers under the circles refer to the number of cases of leukemia that are estimated to have resulted from the radiation. "X-rayed infants" refers to children treated for thymic enlargement. "X-rayed adults" refers to patients with ankylosing spondylitis. (References to the original literature and methods of estimating incidence of radiation-induced leukemia and radiation dose are contained in Science, vol. 125, pp. 965–872. May 17, 1957.)

This chart shows radiation dose along the bottom in the rem unit which Dr. Taylor talked about this morning, essentially the same as the roentgen unit. We use it here because we are going to include some information on atomic bomb survivors whose total irradiation included a percentage due to neutrons, possibly 10 to 20 percent.

Along here we have induced leukemia per million persons per year. The first thing we might consider are the circles. These are people who have died of leukemia as a result of a sudden dose of radiation. We all know about the atom bomb survivors receiving varying amounts of radiation in Hiroshima and Nagasaki as a result of the August 1945 bursts. These points are shown in blue. The largest

number we have is shown here as 39 persons estimated to have died of leukemia as a result of radiation. There were actually in a certain zone in these cities 41 persons who died of leukemia, and who were estimated to have obtained approximately 250 rem units. Of the 41, 39 are those we would estimate died from the radiation. The remaining 2 would have been expected to die as a result of the natural leukemia incidence within the population. This result is based on some 14,000 people. The period of time is almost 8 years. (This is a study from 1948 to 1955—September of 1955—and that is a 7.8 year period).

Representative COLE. Mr. Chairman, in order that we might have a better understanding of the observations which the chart discloses, may I inquire if this chart reflects the studies on all of the people affected by both the atom weapons or 1 of them or a segment of 1 of them? Thirty-nine out of perhaps 5,000 persons might be significant. If it is 39 out of 500,000 it would be less significant. In order to really evaluate and appreciate the significance of the chart I think we should know the extent or the area included in the observation.

Dr. LEWIS. Thirty-nine of the 14,000 in this particular case, sir, is the number of cases of leukemia in a certain zone in both cities—a certain area, namely in this particular case, extending from 1,000 to 1,500 meters from the point on the ground under the bursts. The combined total number of people in this area in both cities was 14,000, approximately, from census estimates in 1950.

I might add that these data have been published by other investigators and collected by a great number of people. The only thing that we do here is to relate incidence of leukemia to dosage. This has not been done before for the reason that the Atomic Bomb Casualty Commission did not have the doses for so relating the incidence of leukemia.

There are 18 cases of leukemia which have arisen in the zone from zero to 1,000 meters from the point on the ground under the aerial bursts in Hiroshima and Nagasaki. There were only approximately 1,800 people who survived in that zone and among these the 18 cases of leukemia accumulated over the 7.8 years. This is about a 1 percent incidence of leukemia. The average absorbed dose in this case is estimated to be about 650 rem.

This point down here represents six people, a very small number of persons as far as our purposes here are concerned, which are to try to relate the dose to the incidence. There were in fact 10 persons who have died already in this region from leukemia, among approximately 23,000 people who were exposed in this dose range. That is, the combined total in the 2 cities of Hiroshima and Nagasaki was 23,000 persons who were beyond the 1,500 meter point and who were between 1,500 meters and 2,000 meters.

Of the 10 persons who died of leukemia, 4 would have been expected to have died on the basis of the spontaneous incidence. That leaves six, which is the expectation for the number who have died from A-bomb radiation. That is a low number and is subject to considerable error. The average absorbed dose in this region is estimated to be only 25 rem, and the maximum possible dose in this region was 100 rem.

I call your attention to the fact that we haven't much information in this part of the curve and yet that is the part of the curve that we are interested in here because we are considering small amounts of radiation.

I will only quickly point out that there have been children who have received a rather large dose of radiation, some averaging possibly anywhere between 100 and 300 of these units. They have an increased rate of leukemia which is statistically significant. There were 7 cases of leukemia in a group of some 1,400 children in this case. These 7 have developed leukemia after having been X-rayed as infants for a chest condition; 6 of these is the number that we would estimate were due to radiation, because at best only less than 1 is expected from the natural incidence of leukemia. I have been referring to a study by Dr. Simpson and associates.

A study is being made in Great Britain by Dr. Court Brown and colleagues of X-rayed adult males who had been treated for a serious spinal abnormality which is alleviated to some extent by this treatment.

In this case we have in the orange circles different treatments given to 11,287 male patients in Great Britain. These are the numbers of individuals, and this [indicating] would be the rate of leukemia. It is a significantly increased rate. They were irradiated only in partial body form to the spinal area, and seemed to develop only the kind of leukemia that stems from the bone marrow and hence it is possible that the total leukemia rate per unit of radiation dose would be higher by a factor of 2 (shown by the dashed vertical lines).

As I said, these are acute doses of radiation—sudden doses. We are interested in slow chronic radiation exposure. We have some evidence on this which has been accumulated again by a number of investigators. I refer to a group of occupationally exposed persons, namely radiologists. The period of time that we are going to talk about is from 1938 to 1952, inclusive. It is estimated that 14 radiologists died of radiation-induced leukemia out of 17 who died of leukemia. That is, three might have been expected according to the spontaneous incidence figures. This is corrected for the fact that we would expect radiologists to have a higher rate of leukemia than the United States white male population owing to differences in age composition.

The long range here means that we do not know what dose radiologists got because, as we know, they got it as a chronic exposure over many years.

I point out that we estimate that somewhere around 250 to 300 r. units or rem units would be the accumulated dose for their mean period of occupational exposure and that period is about 25 years, as it turns out.

Representative Cole. Mr. Chairman, may I inquire with respect to the radiologists over a period of 14 years, from 1938 to 1952? You say that 14 out of 17 radiologists who died from leukemia were traceable to their work. That is a total of 17 radiologists who died as a result of leukemia out of how many radiologists?

Dr. Lewis. 1,860, sir. That population developed from a figure of about 1,300 in 1938 and has increased by 1952 to about 2,500. But the average for that period was 1,860 radiologists. Also, only radiologists who were at ages 35 to 74, inclusive, during the 1938–52 period are considered here.

I want to point out now that one can draw various curves to express these data. I have drawn here a straight-line curve which would say that the incidence of leukemia is directly proportional to the dose. I

feel that the evidence supports this to some extent in the high-dose region. In the low-dose region here, there is a dashed line, and there are only six individuals on which to say anything. The point here, however, is that in the absence of any other information it seems to me—this is my personal opinion—that the only prudent course is to assume that a straight-line relationship holds here as well as elsewhere in the higher dose region.

It may be that there is a threshold—that is, a dose below which leukemia will not develop. However, we can say safely, I think, that if there is a threshold dose it must be below 100 r. The reason for saying that is that in the region below 100 r. you would not expect to have gotten the 6 cases of leukemia as a result of chance more than 1 in 50 times.

I would like to point out one figure that we are very sure of, and that is simply the spontaneous incidence of leukemia in this country. This is 10,000 deaths from leukemia per year in the United States in 1954. It is actually 10,500, but in round numbers 10,000 is the number who die of leukemia in this country at the present time.

If we use this straight line and assume it is a straight line in the low-dose regions—as far as I can see there is little reason to believe that this is not the correct assumption in this region—then we can make some simple calculations, making use of that line. These calculations come out as follows:

One thousand deaths from leukemia per year is what we would expect from natural background radiation. The natural background radiations include cosmic rays, and radiation from rocks, buildings, and the radioactive isotopes in the human body. We receive a dose rate of 100 millirem, or one-tenth of an r. unit, per year from such sources. That is approximate. It varies somewhat from place to place and from time to time and therefore it is not quite clear what the precise figure is.

We see from this that if the straight-line relation holds, there are a fair number of cases actually attributable to the natural radiation. There are some other figures here that are of interest. The figure that we were given of 14 million rem per million people per generation this morning by Dr. Taylor would work out to be approximately five-tenths of a rem per year—not quite—0.47 rem per year. That would be the new public's permissible dose that was mentioned, I believe, particularly with the gonadal dose in mind. But you can't avoid that dose for the whole body as well in most procedures, so that such a dose leads to a sizable number of leukemia cases compared to the spontaneous incidence.

Representative HOLIFIELD. What does that lead to? What would be the number that five would lead to? Would it be 5 times 1,000?

Dr. LEWIS. Do you mean this? [indicating], namely 5,000 cases per year.

Representative HOLIFIELD. Yes. Assuming that 0.5 r. per year is the burden of your argument that it would increase the 1,000 cases to 5,000 per year.

Dr. LEWIS. It would add the 5,000 to the 10,000 total. The new proposed permissible dose for the United States public, would lead to 5,000 cases per year on this calculation, of which 1,000 cases per year would be due to the natural background. So 4,000 cases per year would be the added rate.

As far as fallout is concerned, which is the relevant thing today, I think 0.001 r. is a conservative rate per year that one can estimate we have at the present time reached on the basis of an estimate that was given to the Genetics Committee of the National Academy of Sciences; namely, that the United States now gets one-tenth of an r. per generation—per 30 years—from fallout. One-tenth of an r. per 30 years corresponds to three one-thousandths of an r. per year. I have not used 0.003 because it is possible that the whole body absorption dose would be less than this. So we take 1 milliroentgen (0.001 r.) per year as a conservative rate. Then if we reach this level and maintain it continuously, that leads to 10 as the number of deaths from leukemia per year from fallout sources. We have not had this exposure long enough to make it 10 per year as yet. This exposure would have to go on for 60 years. That sounds like a long period of time. However, radiation from strontium 90 in the bones will help to contribute at least this high a dose rate for quite a while to come because of the retention of strontium 90 in the bones and because of its long half-life (28 years).

This particular estimate of 10 deaths from leukemia per year at the present fallout rate would not be this high at the present moment in the United States. I do not think it would be higher than 1 to 3 deaths per year at the present time from fallout that has accumulated so far. In terms of our population that is a very minute fraction of the population—an exceedingly minute fraction—but after all, it does correspond to somebody.

Thank you.

Representative HOLIFIELD. Thank you very much, sir.

Senator ANDERSON. Did you say if a threshold exists at all it must be below 100 r. for the Hiroshima-Nagaski victims?

Dr. LEWIS. Yes, sir.

Senator ANDERSON. Is that not about the lowest we have had yet on that?

Dr. LEWIS. I think it is for human beings. There are data indicating that in mice such a dose would be still lower.

Senator ANDERSON. I am talking about human beings.

Dr. LEWIS. Yes.

Representative HOLIFIELD. In the concluding part of your statement you say that if the present population of the United States were to be constantly exposed to 100 sunshine units of strontium 90, the prediction calculated in this way is that 500 to 1,000 cases of leukemia would occur annually from this source alone.

The direct proportionality law further predicts that constant exposure to 1 sunshine unit of strontium 90 would be capable of producing from 5 to 10 cases of leukemia annually in the United States population. You have illustrated that by the chart.

So the position that you take, then, is that any radiation would have an effect and that therefore there is a threshold.

Dr. LEWIS. Is not a threshold.

Representative HOLIFIELD. Is not a threshold, I should say.

Dr. LEWIS. That is right. The threshold concept would say that you would not get any leukemia at all until you reach, say 500 r., which in a sense was the assumption when it was thought you could safely accumulate radiation as an occupational worker at a rate of 15 r. per year. Now we have more information that says, no, the threshold

dose had better be put well below 500 r. I would say we must put it well below 100 r.; in fact, I doubt that a threshold exists.

As far as I can see from analogy with phenomena of genetics, which is my field, there is a possible theoretical basis for predicting that there would be no threshold, namely, if leukemia is due to a somatic mutation. That is the interest of geneticists in this disease. However, these calculations do not assume that leukemia is due to a mutation. It does not matter what leukemia is due to; if this line continues as a straight line to zero then these calculations are valid.

Representative HOLIFIELD. Are there any further questions?

If not, thank you, Dr. Lewis.

(A statement and an article entitled "Leukemia and Ionizing Radiation," by Dr. Edward Lewis, follows:)

STATEMENT BY E. B. LEWIS, JUNE 3, 1957

Exposure of human beings to radioactive fallout is expected to have two types of biological effects: (1) genetic effects on the descendants of the exposed individuals, and (2) direct effects on the exposed individuals themselves. The present testimony is restricted to considering one of the direct effects; namely, the induction of a specific malignant disease, leukemia.

In recent years, a number of investigators have been making careful followup studies of persons who are known to have been exposed to man-made sources of radiation. These studies have provided us with abundant evidence that radiation induces leukemia in man. The following four groups of people have been the principal ones investigated: (1) survivors of the atomic bomb bursts over Hiroshima and Nagasaki; (2) patients irradiated with X-rays for the purpose of alleviating a spinal abnormality (ankylosing syondylitis); (3) children irradiated with X-rays as infants for the purpose of alleviating an enlarged thymus gland; and (4) radiologists, who, of course, are occupationally exposed to ionizing radiations.

For each of the above four groups of persons, it is possible to make estimates of the doses of radiation which they received and then to relate such estimates to the number of cases of leukemia that developed subsequent to the irradiation. When this is done, it is found that the incidence of the disease tends to vary in direct proportion to the dose of radiation. That is, doubling the dose tends to double the number of people who will develop radiation-induced leukemia, other factors being equal.

The Japanese survivors and the X-rayed patients were subjected to sudden doses of radiation, whereas the radiation from current levels of radioactive fallout is expected to be delivered gradually over many years with only a very small amount occurring at any one instant. How effective, then, is chronic irradiation in producing leukemia? Radiologists have received their radiation as a chronic occupational exposure extending over many years and in relatively small amounts at any one time. Yet, radiologists die of leukemia at a rate which is about five times that expected if they had received no occupational exposure to radiation. Also, radiologists seem to have about the same chance of developing leukemia, after a given dose of radiation, as do the survivors of atom-bomb radiation or the patients treated with X-rays.

The above findings suggest that the small amounts of radiation which are expected to accumulate from radioactive fallout may also be effective in producing leukemia. It should be noted here that there are two routes by which fallout may exert its effects. Mixed fallout products outside the body emit long-range or gamma radiation which then can cause whole-body irradiation. Fallout products also emit short-range radiation which will be effective as far as leukemia is concerned when the fallout products are ingested into the body. Here, radiostrontium is especially important since it accumulates near the bone marrow where certain types of leukemia are thought to originate.

Recently there have been suggestions that the public would not suffer any appreciable effects if the body level of strontium 90 were to reach 100 sunshine units of this element—this is an amount which is one-tenth that permitted workers with radioactive materials. Now, if the direct proportionality law continues to hold at even the lowest dose levels—and there is little reason to believe it will not hold—then it becomes possible to calculate the number of cases of leukemia

that will arise if, for example, the present population of the United States were to be constantly exposed to 100 sunshine units of strontium 90. The prediction calculated in this way is that 500 to 1,000 cases of leukemia would occur annually from this source alone. The direct proportionality law further predicts that constant exposure to even one sunshine unit of strontium 90 would be capable of producing about 5 to 10 cases of leukemia annually in the United States population.

Leukemia and Ionizing Radiation [1]

(By E. B. Lewis)

Quantitative estimates of the genetic effects of ionizing radiation on human beings have been carried out by a number of investigators (1–3). Estimates of this kind involve extrapolating from induced mutation rates in such organisms as *Drosophila* and mice. Quantitative estimates of the somatic, or direct, effects of radiation must also be attempted if the biological hazards of ionizing radiation are to be fully assessed. In the case of direct effects, it is particularly difficult to extrapolate from results with lower organisms, and it becomes important to have data on man himself.

It is the purpose of this article to examine the evidence for the induction of leukemia in man by ionizing radiation. Although ionizing radiation has been implicated in the production of other human malignancies, such as bone tumors (4) and thyroid carcinoma (5, 6), only the data on induction of leukemia seem sufficiently extensive to warrant a study at this time of the quantitative relationship between incidence of the disease and dose of radiation. Evidence bearing on this relationship is drawn from studies of leukemia among four groups of individuals: (i) Survivors of atomic bomb radiation in Japan; (ii) patients irradiated for ankylosing spondylitis; (iii) children irradiated as infants for thymic enlargement; and (iv) radiologists. An estimate of the probability of developing leukemia per unit dose of radiation (7) per time unit is derived for each of these groups. This probability of radiation-induced leukemia is discussed and its application to a specific example of a possible radiation hazard—namely radiostrontium—is outlined. Certain properties of the disease, relevant to the radiation studies, are presented first.

DESCRIPTION OF THE DISEASE

Leukemia is a malignant disease in which the leucocytes undergo a more or less unrestricted proliferation. The "acute" form of leukemia differs from the "chronic" form, not only in being usually of shorter duration, but also in being a more severe disease with a higher percentage of immature white blood cells in the circulating blood. Another classification of the leukemias is based on the type of white blood cell predominating in the marrow or in the circulating blood. The two most common of these types are known as granulocytic (or myelogenous) and lymphocytic (or lymphatic). The presumption is that the granulocytic type arises in the red bone marrow. The lymphocytic type is thought to arise in the lymphatic elements of the blood-forming system (thymus, spleen, and other lymph glands), although the marrow is not excluded as a source for this type.

SPONTANEOUS INCIDENCE OF LEUKEMIA

In 1947 Sacks and Seeman (8) reported that the recorded death rate from leukemia had increased steadily from 1900 to 1944 and at an accelerated rate after 1930. The death rate has continued to increase (9). By 1954 the crude mortality rate for leukemia among the United States white population had reached 68 per million individuals per year (10) compared with 42 per million in 1940 (11). The male and female crude death rates in that population were 79 and 58 per million per year, respectively, in 1954 (10). The observed increase in death rate from this disease may be partly due to improvements in diagnosis. Other factors may also be responsible, such as the increased exposure of the population to ionizing radiations employed in medicine and dentistry, as was recently discussed by Dameshek and Gunz (12).

---

[1] Dr. Lewis is professor of biology at the California Institute of Technology, Pasadena.

MacMahon and Clark (18) have recently studied the spontaneous incidence of the common forms of leukemia. They have attempted to determine the total number of valid cases diagnosed among residents of the borough of Brooklyn from 1948 to 1952, inclusive. In this study the over-all ratio of acute to chronic forms among the white population was nearly 1/1 (726/732), but there were marked differences in the incidence of these two forms with respect to age at time of diagnosis, as is shown in table 1 (14). The ratio of granulocytic to lymphocytic types in the Brooklyn study was 1.6/1 (512/318).

LEUKEMIA IN HIROSHIMA AND NAGASAKI

Studies of the incidence of leukemia among survivors of the atomic bomb bursts over Hiroshima and Nagasaki have established that ionizing radiations induce leukemia in man (15–17). Table 2 summarizes the incidence of leukemia in terms of four concentric zones about the hypocenter (the point on the ground under the aerial burst). This table includes only those cases of leukemia which were (i) diagnosed during the period January 1948 to September 1955, inclusive; (ii) resident in the city at the time of diagnosis (Hiroshima) or at the time of death (Nagasaki); and (iii) considered by several criteria to be valid cases of the disease (18). For each zone, the estimate of the number of exposed survivors resident in Hiroshima as of October 1950 (17) has been combined with the corresponding number for Nagasaki (15) to obtain a combined population estimate for both cities.

Lange et al. (16) have studied the pattern of types of leukemia in the exposed and unexposed populations of Hiroshima and Nagasaki. They conclude that radiation induces the same pathological types that are found spontaneously and, as far as can be judged by the limited data, induces them in roughly the same relative proportions that occur spontaneously. This is especially evident in the case of chronic lymphocytic leukemia, which is rare in both the exposed and unexposed Japanese populations, whereas it is the most common form of leukemia after age 50 in the United States (13). Lange et al. found no marked influence of sex or age on the incidence of leukemia among the exposed populations. However, they point out that, for a number of reasons, the data are not very satisfactory for assessing the incidence in individuals under 5 years of age (19).

TABLE 1.—*The spontaneous incidence of leukemia for the white population of Brooklyn, N. Y., 1943–52, according to chronicity—Data of MacMahon and Clark (13)*

Age	Percentage in age interval	Incidence per million per year [1]		
		Acute	Chronic	Total
0 to 9	15.3	48	1	49
10 to 19	13.5	24	2	26
20 to 29	16.5	12	6	18
30 to 39	16.5	20	14	34
40 to 49	14.8	22	28	50
50 to 59	11.8	44	64	108
60 to 69	7.6	58	133	191
70 and over	3.9	59	182	241

[1] The incidence of subacute and unknown types of leukemia have been allocated to the observed incidences for the acute and chronic forms in the proportions in which the latter were diagnosed at each age interval (14).

The published accounts of leukemia in Hiroshima and Nagasaki have not contained estimates of the doses received by the bomb survivors. Recently, however, distance-dose curves for these cities have been published (20). These curves give, for each city, the relationship between the slant distance from the burst and the "air" (unshielded) dose of gamma rays and of neutrons. From this information, curves have been constructed (fig. 1) showing the relation between distance from the hypocenter and the combined "air" dose from gamma rays and neutrons (fig. 1) in rem (7). In computing the latter dose, it has been assumed that

the relative biological effectiveness (RBE) of neutrons for inducing human leukemia is 1.7. This value is chosen since Dunning has recently stated that "for generalized whole-body effectiveness it is thought that 1.7 is a reasonable representative value for neutrons from a nuclear detonation" (21). This is believed to be a conservative estimate for the RBE, since Upton et al. (22) found that the RBE for induction of leukemia in mice by fast neutrons is somewhat lower than this.

In the absence of precise knowledge of the distribution of survivors within the different zones about the hypocenter, it is conservative to take the mean "air" dose for a zone as the average "air" dose received by survivors in that zone. The zone from 0 to 999 meters, which is designated here as zone A, is a special case, however, since there was heavy mortality near its center. The mean dose for this zone has been computed for the portion of this zone extending from 850 to 999 meters. The majority of leukemia cases in zone A occurred in this latter region (15); moreover, 2 (among 5) cases at a distance closer than 850 meters had the type of shielding specified, and in each case it was listed as heavy (18). Since the doses for the two cities are slightly different at a given distance from the hypocenter, the average value of these two doses is used without correcting for differences in population size. In this way, a dose of about 1300 rem is arrived at for zone A. For zones B (100 to 1,499 meters) and 3 (1,500 to 1,999 meters), the mean doses are approximately 500 rem and 50 rem, respectively. At 2,000 meters the dose has fallen to 14 rem and by 2,500 meters to less than 5 rem. Since the majority of the population in zone D (from 200 meters on) was beyond 2,500 meters, the average dose is under 5 rem and is thus so low that zone D can be treated as if it were a "control" zone.

The relation of dose, estimated as described in the preceding paragraph, to the incidence of leukemia per year, based on the combined Hiroshima and Nagasaki data, is shown in table 3. The incidence per year in the "control" zone, D, is subtracted from the incidence in each of the other zones to obtain the "incidence of induced leukemia per year" in these zones. The values of the incidence of induced leukemia are likely to be minimum ones, since, as Lange et al. have noted, "some cases of leukemia have undoubtedly been missed and other cases have been omitted because of lack of adequate material to confirm the diagnosis" (16). The incidences of induced leukemia in zones A, B, and C have been divided by the respective means "air" doses in rem, derived in the preceding paragraph, to give estimates for the probability of induced leukemia for these zones. The values for this probability are seen to range from 0.7×10^{-6} to 0.9×10^{-6} per individual per rem per year. These are minimum estimates of the probability of induced leukemia, since the survivors were shielded in varying degrees from the "air" doses, calculated in the preceding paragraph. The shielding of survivors has two major components: (i) the body's own shielding of its blood-forming tissues by the surrounding bone and soft tissues; and (ii) external shielding by buildings or other shelters. A shielding factor of 2 is believed to be a conservative one for correcting for both of these components—the true factor might be at least 4 (23). The "best" estimate for the probability of induced leukemia from these data is, therefore, taken as approximately twice the aforementioned minimum estimates of 2×10^{-6} per individual per rem per year (of the 7.75-year period). A rought range for this probability is 0.7×10^{-6} to 4×10^{-6}.

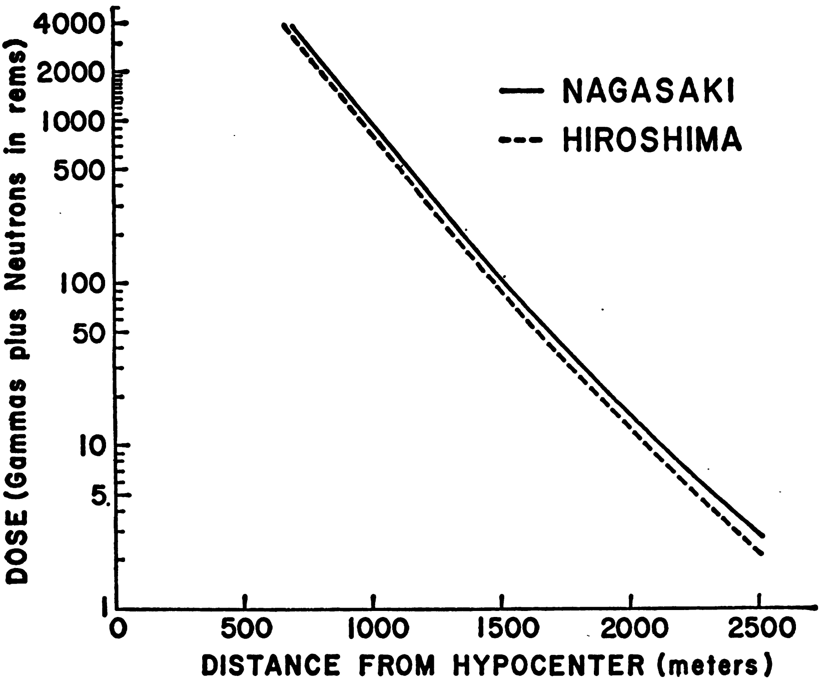

FIGURE 1. Distance-dose curves for atomic bomb blasts at Nagasaki and Hiroshima.

LEUKEMIA AND ANKYLOSING SPONDYLITIS

Court Brown and Doll (24) and others (25, 26) have investigated the incidence of leukemia among patients treated with X-rays for ankylosing spondylitis—a hereditary disease of the spine. Among 11,287 male patients irradiated during the period from 1935 to 1954, inclusive, 37 cases of leukemia were discovered. The average period of followup of these patients was "just under 5 years" (24). The distribution of cases by amount of treatment, measured as maximum dose in roentgens (7) to the spinal marrow, is shown in table 4. A highly significant increase in the incidence of leukemia is apparent among those receiving the heavier treatments.

Court Brown and Doll have estimated the expected incidence of leukemia in a comparable group of unirradiated normal males as 50 cases per million individuals per year. Subtraction of this expected incidence from the observed incidence of leukemia per year in the irradiated patients gives an estimate of the incidence of radiation-induced leukemia per year. This calculation has been carried out for each of the groupings of leukemia cases according to amount of treatment. For each such grouping between 500 and 2,750 roentgens, an average maximum dose to the spinal marrow is taken as the midpoint of the dose range (for example, for leukemia cases developing after treatments ranging from 500 to 999 roentgens, 750 roentgens is taken as the average dose). By dividing the calculated incidence of radiation-induced leukemia for each of the four groupings of this kind (col. 5, table 4) by the respective average maximum dose (col. 2, table 4), a set of four minimum estimates of the probability of leukemia per individual per roentgen (to the spinal marrow) per year is obtained. These latter estimates are seen to range from 0.3×10^{-6} to 0.6×10^{-6} per individual per roentgen per year (col. 6 of table 4). It seems likely that the absorbed dose to the entire red-marrow system would be lower than the stated doses to the spinal marrow by a factor of at least 2 or 3. Therefore, it is estimated that the probability of leukemia ranges from about 0.6×10^{-6} to 2×10^{-6} per individual per rad (to the red-marrow system) per year.

TABLE 2.—*Incidence of leukemia among the combined exposed populations of Hiroshima and Nagasaki by distance from the hypocenter (January 1948–September 1955)*

Zone	Distance from hypocenter (m)	Estimated population of exposed survivors (October 1950)	Number of confirmed cases of leukemia	Percentage of leukemia
A	0 to 999	1,870	18	0.96
B	1,000 to 1,499	13,730	41	.30
C	1,500 to 1,999	23,060	10	.043
D	2,000 and over	156,400	26	.017

TABLE 3.—*Incidence of leukemia per year among the combined exposed populations of Hiroshima and Nagasaki (January 1948 to September 1955) in relation to dose of radiation (gammas plus neutrons)*

Zone	Average maximum dose (rem)	Incidence of leukemia per million per year	Incidence of radiation-induced leukemia per million per year	Probability of leukemia per individual per rem per year
A	1,300	1,200	1,179	0.9×10^{-6}
B	500	390	369	$.7\times10^{-6}$
C	50	56	35	$.7\times10^{-6}$
D	5	21		

LEUKEMIA AND THYMIC ENLARGEMENT

Simpson et al. (6) have traced a series of 1,400 individuals who had irradiated as infants for an enlarged thymus condition. The average period of followup appears to have been about 15 years. As a "control" 1,795 unirradiated siblings were also traced. In the irradiated group there were 7 confirmed cases of leukemia (and 1 unconfirmed case), while there was none in the control group. The calculated number of cases of leukemia that would have been expected in a sample of comparable size and age from the general population was 0.6. The difference between this expectation and the observed number of cases (seven) is statistically significant (P less than 0.01).

In the majority of the 1,400 infants, the radiation (X-rays) had been more or less restricted to the chest region. It was estimated that the air dose to the thymus region was more than 200 roentgens ("the great majority being less than 600 r") in 57 percent of the treated individuals and under 200 roentgens in the remainder. The average absorbed dose to the entire lymphatic system is roughly estimated as 100 to 300 rad. On the basis of these dose estimates, the probability of leukemia ranges from 1×10^{-6} ($6.4/15\times1{,}400\times300$) to 3×10^{-6} per rad (to the lymphatic system) per individual per year. The number of cases (seven) on which this estimate is based is, of course, small. The 95-percent confidence interval for an observation of 7 when the frequency is as low as in the present case lies between 3.3 and 13.2 (27). Therefore, the probability of leukemia in the thymic enlargement group may well range from 0.4×10^{-6} to 6×10^{-6} per rad (to the lymphatic system) per individual per year.

LEUKEMIA AMONG RADIOLOGISTS

March (28, 29) and others (30, 31) have called attention to the fact that among physicians the percentage of deaths from leukemia is much higher for radiologists than for physicians who are not radiologists. The percentage of deaths that are due to leukemia can be a misleading statistic, however, since it is sensitive to differences in age distribution between the groups of individuals being compared. Such differences are marked in the case of radiologists, on the one hand, and all physicians, on the other, as is discussed later. To assess the radiation factor in the leukemia among radiologists, it becomes necessary to

estimate (i) the death rate from leukemia among radiologists (the number of deaths per total number of living radiologists), and (ii) the expected death rate from leukemia among radiologists if they had received no occupational exposure to radiation.

TABLE 4.—*Incidence of leukemia among ankylosing spondylitis patients receiving different doses of radiation (X-rays)—Data from Court Brown and Doll (24)*

Maximum dose to spinal marrow (r.)	Estimated average maximum dose (r.)	Number of males developing leukemia	Crude incidence per million males per year	Incidence of radiation-induced leukemia per million males per year	Probability of leukemia per individual per r. (to spinal marrow) per year
0			50		
Under 500		2	220	170	
500-999	750	8	410	360	0.5×10^{-6}
1,000-1,499	1,250	8	420	370	0.3×10^{-6}
1,500-1,999	1,750	8	1,130	1,080	0.6×10^{-6}
2,000-2,749	2,375	6	1,300	1,250	0.5×10^{-6}
2,750 or more		5	1,760		

The study of motality among medical specialists by Dublin and Spiegelman (32) has been used here as a guide in computing the afore-mentioned rates and as source of data for the years 1938 to 1942, inclusive. The latter data and additional data for the years 1943 to 1952, inclusive, are summarized in table 5. The term radiologist is restricted here, following Dublin and Spiegelman, to those physicians who were listed in editions of the American Medical Directory (33) as limiting their practice to radiology (and roentgenology). Since only deaths occurring at ages 35 to 74 years, inclusive, were included in the mortality study for 1938–42, the same practice is adopted here for the supplementary 10-year period.

In order to estimate the mean annual population of radiologists at ages 35 to 74 years, during the entire 15-year period from 1938 to 1952, the age distribution of radiologists is required. This age distribution for the year 1940 was computed by Dublin and Spiegelman from the 1940 edition of the American Medical Directory and is shown in table 6. The age distribution for a similar group of radiologists in 1950, also shown in table 6, has been computed (34) by reference to the 1950 edition of this directory. The 1940 age distribution was based on a total of 1595 radiologists of whom 1451.5 (91.0 percent) can be inferred to have been at ages 35 to 74 years, inclusive (32). The 1950 age distribution was based on a total of 2443 radiologists of whom 2250 (92.1 percent) are calculated to have been at ages 35 to 74 years, inclusive, as of July 1, 1950. The mean number of radiologists (at ages 35 to 74) per year from 1938 to 1952, inclusive, is roughly approximated as 1850.7, which is the average of the number of such radiologists in 1940 and the corresponding number in 1950.

Deaths from leukemia occurring at ages 35 to 74 years, inclusive, among radiologists have been located in several ways with the results shown in table 5. For the period from 1938 to 1942, inclusive, five such deaths are recorded by Dublin and Spiegelman. For the period from 1943 to 1948, inclusive, the carefully documented studies of March (28, 29) record eight such deaths. For the remaining 4-year period from 1949 to 1952, inclusive, four additional deaths from leukemia have been located by reference to death notices in a medical journal (35). Thus, a minimum of 17 deaths from leukemia has been located among radiologists who died between the ages of 35 and 74 years during the 15-year period from 1938 to 1952. The upper and lower 95-percent confidence limits for this observation of 17 deaths are 25.5 and 10.8 deaths, respectively (27). Thus, a likely range of values for the average death rate from leukemia among radiologists at ages 35 to 74 years is 390 ($10.8/15\times1850.7$) to 920 ($25.5/15\times1850.7$) deaths per million per year, and the "best" estimate is 610 ($17/15\times1850.7$) deaths per million per year (of the 1938–52 period).

TABLE 5.—*Deaths and death rates from leukemia among radiologists, at ages 35 to 74 years, by 5-year periods from 1938 to 1952, inclusive*

Period	Estimated number of radiologists at mid-point of period	Number of deaths from leukemia	Observed death rates per million per year	Expected death rates per million per year	Incidence of radiation-induced deaths per million per year
1938–42	1,451.5	5	690	101	589
1943–47	[1] (1,850.7)	6	650	[1] (121)	429
1948–52	2,250.0	6	530	141	389
(1938–52)	[1] (1,850.7)	17	610	[1] (121)	489

[1] The arithmetic average of the values for the 1938–42 and 1948–52 periods.

The expected death rate from leukemia among radiologists, if they had received no occupational exposure to radiation, is estimated by first calculating the death rate they would have experienced if subject to United States white male death rates from leukemia. This calculation has been made for a 3-year period from 1939 to 1941 by first computing (36) the mean annual age-specific United States white male death rates from leukemia (table 7) and then applying them to the 1940 age distribution of radiologists (table 6), restricting the computation to the 35- to 74-year age interval. The resultant expected death rate for the latter age interval is 63 deaths per million per year.

The same type of calculation has been carried out for a 3-year period from 1949 to 1951 by computing (36) the appropriate age-specific death rates for that period (table 7) and applying them to the 1950 age distribution of radiologists. The resultant expected death rate is 88 deaths per million per year.

The average of the rates for the 1939–41 and 1949–51 periods is 76 deaths per million per year. The latter rate should roughly approximate the mean annual death rate from leukemia which radiologists would have experienced during the 1938–52 period if they had been subject to United States white male death rates for this disease. The observed death rate for this period was 610 deaths per million per year (table 5), which is 8 times the expected rate, just calculated.

It is possible, however, that reasons other than radiation exposure may account for the high death rate from leukemia among radiologists. For example, leukemia might be more likely to be diagnosed among radiologists than among the group of all United States white males. To correct for such possibilities as this, the expected death rate of 76 deaths from leukemia per million per year, calculated in the preceding paragraph, is multiplied by a correction factor of 1.6. This factor is the ratio of the observed number of deaths from leukemia among physicians who were nonradiologists to the expected number of deaths calculated on the assumption that such physicians were subject to United States white male age-specific death rates for leukemia.

This factor of 1.6 has been inferred from data for the 1938–42 period given by Dublin and Spiegelman (32) and is applied throughout the entire 15-year period from 1938 to 1952 to give the expected death rates shown in table 5. It is a conservative factor in the sense that it is possible that the increased death rate from leukemia among physicians who are nonradiologists is partly due to exposure of some of them to ionizing radiation (31). Thus, 121 (1.6×75.5) deaths per million per year is probably a conservative estimate of the expected death rate from leukemia among radiologists in the 1938–52 period, if they had received no exposure to radiation.

The expected death rate from leukemia, just calculated, would be expected to yield 3.4 ($15\times1850.7\times121\times10^{-6}$) deaths among radiologists during the 1938–52 period. It is appropriate at this point to compare this with the observed number; namely, 17 deaths (table 5). The probability of observing 17 or more when the expected number is 3.4 is readily obtained from the Poisson distribution and is found to be less than 1×10^{-6}. Hence, the observed value exceeds the expected value at a statistically highly significant level.

The difference between the expected death rate from leukemia calculated on the assumption of no occupational exposure to radiation and the observed death rate is designated the "incidence of radiation-induced leukemia," L. For a stationary population chronically irradiated at a constant dose rate, D, the incidence, L, can be approximated if it is assumed that the probability of leukemia per rad of accumulated dose per year, P_L, is a constant for all age groups in the population and for all values of the accumualted dose. On these assumptions, a sta-

tionary population exposed for a mean number of years, E, to the dose rate, D, will have an incidence of radiation-induced leukemia that can be expressed as follows:

$$L(=)(D)\cdot(E)\cdot(P_L)$$

To estimate the value of E, it is assumed that occupational exposure of radiologists starts at age 25 and ends at age 65. The value of E for individuals who were at ages 35 to 74 in 1940 can then be approximated from the age distribution of radiologists for that year (table 6) and is found to be 24.7 years. The corresponding value of E approximated from the 1950 distribution (table 6) is 24.1 years. The average of these 2 values, 24.4 years, is used as the value of E for the population of radiologists who were at ages 35 to 74 years in the 1938–52 period. The best estimate of L is 489 deaths per million per year (table 5), and a likely range of values for L is 270 to 800 deaths per million per year, based on the 95-percent confidence limits for the observed death rate of 610 deaths per million per year. For reasons discussed later, the value of D is estimated to lie between 3 and 30 rad per year.

The best estimate for the range of values of P_L is then given by the expression

$$P_L \text{ (likely range)} = \frac{489}{24.4\times(3 \text{ to } 30)} = (0.7 \text{ to } 7)\times10^{-6}$$

per individual per rad per year

A broader range, based on the confidence limits for L, is $(0.4 \text{ to } 11)\times10^{-6}$ per individual per rad per year.

TABLE 6.—*Age distribution of radiologists in 1940 (32) and 1950*

Age	Percentage distribution as of	
	1940	1950 (July 1)
Under 35	8.3	6.1
35 to 44	31.3	38.9
45 to 54	33.8	26.6
55 to 64	19.8	18.7
65 to 74	6.1	7.9
75 and over	0.7	1.8
Total	100.0	100.0

Since the dose rate, D, in the foregoing discussion, represents the average absorbed dose rate to the leucocyte-producing system, it is likely to be lower by at least a factor of 2 than the "air" dose rate to which radiologists were exposed. The recommended maximum dose rate (in air) for such workers was set at 0.2 roentgen per day in 1931 by the United States National Committee on Radiological Protection; this rate was reduced to 0.1 roentgen per day in 1936 and to 0.05 roentgen per day in 1949. Although some radiologists may well have exceeded the recommended dose rates, it seems unlikely that the average dose rate for all radiologists in the group under consideration would have exceeded the permissible limits set in 1931. Thus 30 rad per year has been taken as an upper limit for the absorbed dose to the leucocyte-producing system. The lower limit for D has arbitrarily been taken as one-tenth of this, or 3 rad per year.

This estimate that D might be much less than 30 rad per year is somewhat at variance with the following conclusions from a recent study of longevity among radiologists (37). "In comparison with nonexposed physicians, the shortening of life of radiologists is 5.2 years, or 11 percent of the adult life span (after 20 years). If extrapolation from the animal data * * * is permissible, this would be expected to result from chromic whole-body exposure to about 1.5 LD_{50} dose, or possibly 1,000 roentgens. Although this exposure was partial body and possibly less effective, it seems unlikely that the equivalent whole-body exposures differed from the above value by a factor greater than 2 or 3. Consequently, it appears that, within these limits at least, extrapolation from short-lived animals to man may be made with some confidence on the basis of percent life shortening per unit dose."

The shortening of life by 5.2 years just cited is based on the observation that during the period 1930–54 the difference between the mean age at death of physicians estimated to have had "no known contact with radiation" and the mean

age at death of radiologists was 5.2 years (37). It can be calculated (38), however, that a difference of at least 6 years would be expected in this case solely as the result of differences in age distribution (as of 1940 or 1950) between radiologists, on the one hand, and all physicians, on the other. That is, radiologists may have a slightly longer life span than physicians as a whole. Moreover, for the 1938–42 period, Dublin and Spiegelman showed that, after appropriate adjustment for differences in age distribution, the total death rate from all causes was lower for radiologists than it was for all physicians combined; however, this rate was slightly higher for radiologists than it was for all specialists combined. Thus, either a chronic whole-body exposure of 1,000 roentgens does not have a marked effect on longevity or, more probably, radiologists have averaged much less than this as a lifetime absorbed dose.

TABLE 7.—*United States white male death rates from leukemia per million per year*

Age	Period	
	1939–41	1949–51
25 to 34	18	26
35 to 44	29	34
45 to 54	55	68
55 to 64	104	149
65 to 74	154	276
75 plus	181	385

Discussion

Table 8 summarizes the various estimates of the probability of leukemia derived from the four sets of data reviewed here. For acute whole-body irradiation the best estimate of this probability will be taken as 2×10^{-6} per individual per rad per year. This value is based on the studies of leukemia among the survivors of atomic-bomb radiation. For acute partial-body irradiation, the available data are conveniently discussed in terms of a probability of leukemia "of bone-marrow origin" (ankylosing spondylitis patients) or a probability of leukemia of "lymphatic origin" (thymic-enlargement patients).

As has already been noted, granulocytic and lymphocytic leukemias may have bone-marrow and lymphatic origins, respectively. Since these two types of leukemia constitute the majority of all leukemias and occur in proportions which are, for present purposes, roughly equal, it is assumed that the best estimate of the probability of leukemia of bone-marrow origin is one-half of that for all leukemia, or 1×10^{-6} per individual per rad to the red marrow per year. Similarly, the best estimate of the probability of leukemia of lymphatic origin is taken as 1×10^{-6} per individual per rad to the lymphatic system per year.

These estimates fall within the range of values calculated for either the ankylosing spondylitis patients or the thymic-enlargement patients. Moreover, there is some evidence that leukemia following irradiation of the spinal marrow is primarily granulocytic (26). Whether lymphocytic leukemia predominates in the thymic-enlargement series (6) is uncertain on two grounds: (i) It is difficult to differentiate granulocytic and lymphocytic types in infants and children; and (ii) some irradiation of bone marrow would, in any case, be expected in this series of patients (39). Finally, the best estimate of the probability of leukemia following chronic whole-body irradiation is taken as identical with that for acute whole-body irradiation—namely, 2×10^{-6} per individual per rad (of accumulated dose) per year. This value is seen to be close to the lower limit of the range of values deduced for radiologists.

Simpson et al. (6) and Court Brown and Doll (24) point out that their studies lack a control in the form of an unirradiated series of patients. Thus, the possibility is not excluded that thymic-enlargement and ankylosing spondylitis predispose toward leukemia. However, a comparison of the various estimated ranges for the probability of leukemia (table 8) suggests that patients with the aforementioned conditions are no more prone to develope leukemia than are radiologists or the Japanese survivors.

Presently available determinations of the incidence of induced leukemia per year are based on average followup periods that are comparatively short in

terms of the normal human life span. Thus, the probability of leukemia per individual per rad per year may not be constant for an indefinite period beyond the initial time of irradiation. By choosing the lower limit for the probability of leukemia at about 0.7×10^{-6} per individual per rad per year, it is felt that adequate account is taken of the possibility that the incidence of leukemia per year following an acute dose of radiation may, as some have sugegsted on the basis of the data from Hiroshima (37), reach a peak followed by a steady decline. It is noteworthy, however, that Court Brown and Doll have concluded, from an analysis of 108 cases of leukemia among the exposed populations of Hiroshima and Nagasaki, that "the data provide no evidence of a sharp peak in incidence at any particular period after the explosion nor any clear indication that the incidence had yet begun to diminish by the end of the ninth year" (40).

The probability of leukemia per individual per rad per year is nearly constant over a rather wide range of doses in the case of the Japanese survivors (table 3) and in the case of ankylosing spondylitis patients (table 4). This is presumptive evidence that the relationship between incidence of induced leukemia and dose of radiation is either linear or approximately linear. A striking feature of the Japanese data shown in table 2 is that the incidence of leukemia in zone C—the zone with a calculated average "air" dose of 50 rem—is significantly higher than in zone D, the control zone ($P=0.02$, by the Chi-square test). Thus, these data provide no evidence for a threshold dose for the induction of leukemia. Moreover, chronic irradiation at a relatively low dose rate (perhaps 0.1 rad per day or less) appears to induce leukemia in radiologists at a rate per rad which is comparable to that observed for the Japanese survivors. This finding also fails to support the concept of a threshold dose below which leukemia will not develop.

A linear relationship between the incidence of leukemia and dose of radiation, which is suggested by the available data for man, may have its explanation in a somatic mutation hypothesis (41). Thus, radiation-induced leukemia may result from a somatic gene mutation, presumably occurring in one of the precursor cells destined to give rise to mature leucocytes. Such a mutation might cause the cell, or its descendants, to acquire an unregulated growth habit, or to release, or to respond to, viruslike or hormonal agents—to mention only a few of many possibilities. Thus, the somatic mutation hypothesis and other hypotheses for the origin of radiation-induced malignancies (42) are by no means mutually exclusive. Gene mutation has long been known to show a linear relationship with respect to dose of ionizing radiation from studies with *Drosophila*. This linearity has been extended by Spencer and Stern (43) to doses of 50 and 25 roentgens. Gene mutation is also known to be directly proportional to the accumulated dose of radiation, even when the radiation is chronically administered at a relatively low dose rate, as in the studies of Uphoff and Stern (44).

The concept of somatic mutation is also helpful in attempting to explain the long period of time which sometimes intervenes between irradiation and onset of leukemia. Thus, it may be that some of the precursor cells of leucocytes lie quiescent for years before they are brought into leucocyte production. A somatic mutation in such a cell might, therefore, be long delayed in producing its effect.

In leukemia of spontaneous origin, there is also likely to be a somatic mutation component which would be attributable to spontaneous mutation in the somatic cells. In addition, there is likely to be a hereditary component in spontaneous leukemia—that is the presence of defective genes (dominant or recessive) which are transmitted through the germ line and which result in, or predispose toward the development of, leukemia. It is well known from the work of MacDowell and associates (45) that the pronounced differences among certain strains of mice in suspectibility to leukemia have a genetic basis. In man, there is evidence for familiar factors in leukemia from the work of Videbaek (46) and others, but the type of inheritance involved is not clear (47). It should be noted that cases of leukemia which arise somatically—for example, those which are radiation induced—will tend to obscure the analysis of the hereditary component in leukemia (48).

It is likely that there will be individual differences in susceptibility to radiation-induced leukemia as well as to spontaneous leukemia. The indication of a linear relationship between dose of radiation and incidence of leukemia implies that there are some individuals in whom a single radiation-induced event (per-

haps a gene mutation) suffices to produce leukemia. There may, however, be other individuals in whom two or more such events would be required before leukemia would be manifested. Thus, the values of the probability of leukemia per individual per rad per year that have been derived here apply to the average individual in a given population, but do not necessarily apply equally to each and every individual in that population.

SPONTANEOUS LEUKEMIA AND NATURAL BACKGROUND RADIATION

The possibility that a portion of the spontaneous incidence of leukemia may be due to radiation from natural background sources is briefly considered. For this purpose, the same type of approximation procedures employed for assessing radiation-induced leukemia among radiologists is applied to the data of MacMahon and Clark on the spontaneous incidence of leukemia in the white population in the borough of Brooklyn (table 1). Thus, the incidence of leukemia, L_B, that would be attributable to irradiation of that population from natural background sources can be approximated by assuming that it is a product of the following three quantities: (i) A constant dose rate, D_n, from all natural background sources; (ii) the mean age, E_B, of the Brooklyn population, which is equivalent to the mean number of years exposed to D_n; and (ii) the probability of leukemia, P_L per individual per rad per year. The value of D_n is not known but probably is in the range of 0.1 to 0.2 rad per year (49). The value of E_B can be readily approximated from the age distribution (table 1) of the Brooklyn population, and is about 33.7 years. The value of P_L is chosen as the best estimate from the aforedescribed radiation studies, namely 2×10^{-6} per individual per rad per year. Thus, L_B can be estimated as 7 to 13 cases per million per year. The observed total spontaneous incidence in this study was 64.4 cases per million per year (13). Thus, possibly 10 to 20 percent of the spontaneous incidence of leukemia in this Brooklyn population is attributable to ionizing radiation from natural background sources.

A maximum value for the probability of radiation-induced leukemia may also be inferred from the Brooklyn data. The calculation of such a value is based on the incidence of acute leukemia, since in this form of the disease the time of onset and time of diagnosis probably nearly coincide, while in chronic leukemia some years may elapse between these two times. The observed incidence of acute leukemia has a minimum value of 12 per million per year which occurs in the 20–29 age group (table 1). By assuming that individuals in that age group had an average accumulated dose of not less than 2.5 rad (0.1 rad per year for 25 years) and by further assuming, as an artifice, that all of the acute leukemia in that age group was due to radiation, the probability of acute leukemia may be estimated to have an upper limit of 5×10^{-6} ($12\times10^{-6}/2.5$) per individual per rad per year. Since the overall ratio of acute to chronic forms was about 1/1 in the Brooklyn data, it may be inferred that the maximum value, or upper limit (table 8), of the probability of leukemia (acute and chronic) is about 10×10^{-6} per individual per rad per year.

APPLICATION TO RADIOSTRONTIUM EXPOSURE

The foregoing estimates of the probability of radiation-induced leukemia have been attempted in order to have some basis for assessing direct effects of ionizing radiations on human populations. An example of the application of these estimates to a manmade radiation exposure—namely, that from radiostrontium (Sr–89 and Sr–90)—is briefly discussed (50).

The maximum permissible concentration (MPC) of Sr–90 has been set at 1 microcurie for the total body for workers with radioisotopes (51). A level of 1 microcurie of Sr–90 per 1,000 grams of calcium (the mass of calcium in the average adult individual) has been designated as 1 "MPC" unit of Sr–90 (52). Various estimates are at hand for the level of radiostrontium that is being accumulated in the human body as the result of past testing of atomic weapons (53). The present discussion is restricted to examination of the following recent suggestion for a permissible level (presumably of Sr–90) for the population at large (54). "There seems no reason to hesitate to allow a universal human strontium (very similar chemically to calcium) burden of one-tenth of the permissible, yielding 20 rep in a lifetime, since this dose falls close to the range

of values for natural radiation background. Visible changes in the skeleton have been reported only after hundreds of reps were accumulated and tumors only after 1,500 or more."

A body level of 0.1 MPC is expected to irradiate skeletal tissue at a dose rate of about 0.25 rad per year, on the assumption of uniform distribution of Sr–90 throughout that tissue. Because of the limited range in tissue of the beta particles emitted in the decay of Sr–90 and of its daughter element, Y–90, the leucocyte-producing cells may receive somewhat less than this dose rate, depending on the exact location of such cells with respect to the surrounding calcium of the bone. This reduction factor of perhaps 2, tends to be offset by the fact that ingested Sr–90 is not uniformly distributed throughout the skeletal tissue, but appears instead to be concentrated in regions more actively concerned with red-marrow formation (55). The dose rate to the leucocyte-producing cells is estimated as 0.1 to 0.2 rad per year for a body level of 0.1 MPC of Sr–90. This irradiation will be largely restricted to the skeletal tissue, since (i) the radiation from the decay of Sr–90 is exclusively of the beta type and (ii) 70 percent of the Sr–90 in the body is estimated to lie in the skeletal tissue (51). Hence, leukemia induced by Sr–90 would be expected to be largely of bone-marrow origin (56).

TABLE 8.—*Summary of the estimates of the probability of radiation-induced leukemia per individual per rad per year*

Source of estimate	Type of radiation	Region irradiated	Types of leukemia produced	Probability of leukemia of specified type per individual per rad (or rem) to region irradiated per year		
				Estimated range		Best estimate
				Lower limit	Upper limit	
Atom-bomb survivors	Gamma rays plus neutrons	Whole body	All	0.7×10^{-6}	3×10^{-6}	2×10^{-6}
Ankylosing spondylitis patients	X-rays	Spine	Granulocytic (only?)	0.6×10^{-6}	2×10^{-6}	1×10^{-6}
Thymic enlargement patients	do	Chest	Lymphocytic (only?)	0.4×10^{-6}	6×10^{-6}	1×10^{-6}
Radiologist	X-rays, radium, etc	Partial to whole body	All (?)	0.4×10^{-6}	11×10^{-6}	2×10^{-6}
Spontaneous incidence of leukemia (Brooklyn, N. Y.).	All natural background sources	Whole body	do		10×10^{-6}	2×10^{-6}

The problem of assessing the incidence of Sr–90-induced leukemia from a constantly maintained level of Sr–90 is essentially identical with that dealt with here for determining the component of the spontaneous incidence of leukemia owing to natural background radiation. Thus, the incidence of Sr–90-induced leukemia in a stationary population maintaining a constant level of 0.1 MPC of Sr–90 is considered to be the product of (i) a dose rate of 0.1 to 0.2 rad per year to red bone marrow; (ii) a mean age for the stationary population of 31.7 years, which is that expected from the age distribution of the total United States white population as of July 1, 1955 (57); and (iii) a probability of leukemia of bone marrow origin of 1×10^{-6} per individual per rad to bone marrow per year. This computation gives an incidence of 3 to 6 cases of Sr–90-induced leukemia per million per year. For a population of 1.6×10^{8} individuals, the current population of the United States, the expected number of cases of leukemia induced by a constantly maintained level of 0.1 MPC of Sr–90 would thus be about 500 to 1,000 per year. The range for this estimate is a factor of about 3, giving 150 to 3,000 cases per year. Currently (1954), there are about 10,500 deaths from leukemia per year in the United States population (10). Thus, if Sr–90 induces leukemia of bone-marrow origin at the same rate (per rad as X-rays and radiations from atomic bombs, then a constantly maintained level of 0.1 MPC of Sr–90 would be expected to increase the present incidence of leukemia (in the United States) by about 5 to 10 percent.

SUMMARY

Leukemia in man can be induced by ionizing radiations, and also occurs spontaneously. For the average individual in a population, the probability of developing radiation-induced leukemia is estimated to be 2×10^{-6} per rad (unit of absorbed dose of radiation) per year. The available data from 4 independent sources make it likely that this estimate is valid within a factor of about 3, giving a range from 0.7×10^{-6} to 6×10^{-6} per rad per year. It is pointed out that 10 to 20 percent of the spontaneous incidence of leukemia (Brooklyn, 1943–52) may result from radiation from natural background sources. It is estimated that a 5- to 10-percent increase in the current spontaneous incidence of leukemia would occur if the population were to reach and maintain a body level of Sr–90 amounting to one-tenth of the "maximum permissible concentration."

7. For the sake of consistency, the "rad," the unit of absorbed dose (100 ergs per gram) is adopted. When the relative biological effectiveness (RBE) is not necessarily unity, as in the case of neutrons, the "rem" (roentgen-equivalent-man) is used (rem=rad×RBE). The factor for converting the "r," or "roentgen," to the rad varies with the type of material and energy of radiation [see, for example, F. Ellis, Brit. J. Radiol. 29, 367 (1956)]; since this conversion factor is usually nearly unity (or, in the case of bone marrow, is not easily estimated), the rad is taken as equivalent to the r, for the purposes of this article. The "rep" (roentgen-equivalent-physical) is another unit of absorbed dose (93 ergs per gram of tissue) which is gradually being replaced by the rad.

33. American Medical Directory (Am. Med. Assoc., Chicago, Ill.).

34. The 1950 distribution is based only on radiologists listed in the section of the 1950 American Medical Directory devoted to membership in radiological societies. Each name in that list was looked up in the main body of the directory to determine year of birth and type of specialization. Only those listed as "R*" (an asterisk signifies that practice is limited to radiology) and resident in the continental U. S. were used in compiling the final age distribution. This procedure therefore fails to include radiologists who were nonmembers of radiological societies; however, this deficiency has been taken into account by establishing that the 12 deaths from leukemia from 1943–52, inclusive, were in fact radiologists whose names were listed in the section of the 1940 or 1950 directory devoted to membership in radiological societies. (I am indebted to Alethea Miller, Janet Chaitkin, and Joan Lewis for assistance in compiling the 1950 age distribution.)

35. The procedure was to obtain a list of deaths of members of one of the leading radiological societies and to search for the cause of death in the death notices of the Journal of the American Medical Association. In the period 1949–52, inclusive, only some 70 percent of all such deaths were found to have a cause of death listed. In order to have a conservative estimate of the incidence of leukemia, no correction for this defect is attempted. The four deaths from leukemia in the 1949–52 period have the following volume and page locations in the aforementioned journal: 144, 407; 147, 1065; 148, 218, 151, 488.

36. Death rates from leukemia for the years 1939–41 have been obtained from reference 11 and computed for the 1949–51 period from Vital Statistics of the United States (Federal Security Agency, Washington, D. C., 1949–51). Sources for the living population were Current Population Repts., Series P-25, No. 98 (1954); No. 114 (1955); No. 121 (1955). (U. S. Bur. of the Census, Washington, D. C.)

Representative HOLIFIELD. We are going to have as our next witness Dr. Shields Warren from the Deaconess Hospital in Boston, and he is going to read, as I understand it, a statement from Dr. Jacob Furth on the subject of leukemia.

Dr. Warren, it is a great privilege to have you with us, and we would like to hear from you now.

STATEMENT OF DR. SHIELDS WARREN, NEW ENGLAND DEACONESS HOSPITAL, BOSTON, MASS.[1]

Dr. WARREN. I appreciate this opportunity very very much. I have been impressed that during these useful and well-planned hearings a number of scientists who are interested in radiation are presenting their findings and views. As one who has worked on the injurious effects of radiation since 1925, I am very happy to see the great influx of enthusiastic workers into this field.

I further appreciate the kindness of the committee in allowing me to testify, and I wish to say that I am speaking as an individual, and not for the various groups of which I happen to be a member.

Representative COLE. Mr. Chairman, I wonder if Dr. Warren would mind indicating the identity of these groups and committees of which he is a member, for the record, since it does not appear in his biography.

Dr. WARREN. Yes. I am the representative of the United States to the U. N. Scientific Committee on the Effects of Atomic Radiation. I am the Chairman of the Committee on Pathological Effects, of the National Academy of Sciences Radiation Group. I am also a member of the Committee on Genetics of the National Academy of Sciences. I am a member of the Advisory Committee on Biology and Medicine of the Atomic Energy Commission. Then there are various scientific associations with which I am also associated.

STATEMENT OF DR. JACOB FURTH,[2] PRESIDENT OF THE AMERICAN ASSOCIATION FOR CANCER RESEARCH (PRESENTED BY DR. SHIELDS WARREN)

Dr. WARREN. I think it would be appropriate in view of the fact that we have been hearing a very pertinent discussion of leukemia, to introduce at this point Dr. Jacob Furth's statement. He is an associate of Dr. Sidney Farber and myself, one whom I consider as probably the world's greatest authority on the experimental induction of leukemia. He say as follows:

FACTS

Radiation causes cancer and leukemia and other body changes, but it is also the best means of identifying and controlling many of them. Induction of neoplasms—by that meaning both leukemias and tumors—by radiations is a remote possibility and occurs rarely, while the benefits are immediate and usual; hence, radiation became a tool of medicine no physician or informed patient would want to be without. Most, if not all, increased hazard from radiations resulted from its medical use, a calculated risk well taken; it is steadily diminishing with recognition and dissemination of knowledge as to where the hazards lie.

SPECULATIONS

The statements that there is no threshold injurious dose to somatic cells, and every irradiation, no matter how small will cause cancer and leukemia, as is stated by some geneticists, are mere speculation. This applies also to the statement that even background irradiation is leukemogenic. The available facts allow argumentation of both sides. In my opinion, the statements that background irradiations will induce leukemia are contrary to observations and the reverse is more likely.

Reasons to assume that a threshold exists:

(a) All reported experiments on leukemia induction by irradiation have pointed to the existence of a threshold and none suggested the lack of it.

Dr. WARREN. I might say in addition that Dr. Furth has had access to all of these figures which you have seen on the chart here, and this is one of the conclusions he has come to.

(b) The complex mammalian host is capable of compensating for subtle damage. It has been shown that partial body irradiation is not conducive to leukemia development; the unexposed parts powerfully protect the exposed part. Thus, if direct hits cause mutation, humoral substances either counteract or reverse

---

[2] Began experimental studies of leukemia in 1928; was first or second (if so in independent work) to publish induction of leukemia, ovarian, breast, lung, and pituitary tumors in mice by ionizing radiation. Presented experimental evidence that leukemia is allied to cancer and some leukemias are related to mutations. Has numerous publications 1930–57 on the subject, all essentially confirmed. Presently, is president of the American Association for Cancer Research. Recipient of high awards and fellowships in scientific organizations in recognition of scientific contributions. (From American Men of Science.)

their actions. Were it otherwise, leukemia among physicians and radiologists and others exposed to small doses of X-rays repeated over long periods of time would be manyfold that actually observed. Some radiologists receive thousands and tens of thousands of roentgens while the population at large receives a few r. of background irradiation in a lifetime. Similarly, if cancer induction is simply due to direct hit mutation with no threshold, one would expect a tremendous number of all kinds of tumors in medical personnel and others on parts exposed to radiation; for example, skin cancers on hands. The early radiologists who got such cancers had severe radiation burns with chronic ulcers in which the tumors arose. Some scientists even argue that the cancers arose from the nonirradiated adjacent skin. It deserves emphasis that cancer did not arise on the hands of tens of thousands of people receiving huge quantities in small doses over long periods.

(c) Similarly, leukemia development in experimental animals can be prevented by post irradiation infusion of marrow cells indicating that either direct radiation hit is not enough to cause leukemia or that body defense can somehow counteract this damage.

(d) The very idea that leukemia and cancers result from a direct hit mutation was never solidly proven and is being challenged recently. Newer evidence unquestionably indicates that some indirect factor plays a determining role in development of leukemias or tumors. Heavy irradiation of some organs can injure specific body regulatory mechanisms and cause cancer indirectly, not by mutation.

(e) In case of pituitary or ovarian tumor induction by irradiation, there is no such linear relationship between irradiation dose and response, as is characteristic for mutation. The reverse is true, and there is a clearly defined threshold which is that dose which markedly depresses the function of that organ—about 80 to 50 r. to the mouse's ovary, 30 μc of I–131 to mouse's thyroid.

(f) Human cells are eternally submitted to small doses of endless kinds of mutagenic agents; some are endogenous, as hormones; others are extrinsic, as chemicals in food, industry, drugs, et cetera. Even plastics and food dyes can cause cancer in animals under given experimental conditions. These, too, are believed to cause the neoplasm by somatic mutation, but I know not of a single human cancer proven to be caused by them. As to leukemia, many drugs and industrial chemicals injure blood forming organs and could be responsible for increased incidence of leukemia. We have yet to learn to what extent the endless number of potential carcinogens to which man is exposed contribute to development of neoplasia in man, alone and combined.

(g) Induction of leukemia in mice from radioactive substances as radiophosphorus and radiostrontium has been reported, as might be expected, from large doses of them, but these reports clearly show existence of a threshold.

RECOMMENDATIONS

(1) Since the medical hazards of radiation are worth taking and since these represent the bulk of radiation hazards, that thus far created by bombology, being a minor evil, should be considered as such. While it is agreed that the latter should be eliminated as expediently as possible with preservation of the safety of the free world, the burden of decision rests not with biomedical investigators, but with miltary experts. All biologists admit the potential hazards of all kinds of radiation and merely argue among themselves about the magnitude of the hazard.

(2) I wish to testify that support for long-term research has been, and still is, niggardly, and it is a disappointing struggle to undertake such research. I recommend liberal long-term support of creative scientists, and incidentally, more centers of knowledge in free institutions. Creative knowledge is our best defense.

Dr. Warren. I appreciate your allowing me to read this statement of Dr. Furth into the record, Mr. Chairman.

Representative Holifield. Thank you very much.

Dr. Warren. Then if I could go back to my own statement.

Representative Holifield. Certainly he puts the issue very plain in his presentation there.

Dr. Warren. Yes. He does this on a background of more than 30 years' experience in this field working with leukemia.

Representative COLE. Mr. Chairman, I would like to inquire of Dr. Warren if he could interpret Dr. Furth's comment with respect to the need for long-term research in which Dr. Furth says it is a disappointing struggle to undertake such research. What did he have in mind?

Dr. WARREN. What he has in mind is this: It is much easier to obtain support and much more satisfying for the scientist to work in a field where he can hope to get results in 1, 2, or 3 years, rather than to work with long-term experiments where he may spend his whole life and still come up with an unsatisfactory result at the end of that period of life. This is the sort of thing that makes it so essential to continue on a long-term basis our studies of the population in Hiroshima and Nagasaki. We may get very few results.

I would like to point out that the results at the lower end of the scale that have been used by Dr. Lewis are not considered as actually statistically significant. They may provide a guide, but I would not want to base any firm conclusions on them.

These studies must be continued. But we know that the chances of getting significant results are relatively few. This is a discouraging type of work. It is hard to get support for it because we have to be honest and say it is quite possible that we will spend funds for 20 years and then not have anything to show you. It was that that Dr. Furth was commenting on.

Representative COLE. Thank you.

STATEMENT OF DR. SHIELDS WARREN—Resumed

Dr. WARREN. I would like to make it clear that much has been learned about radiation effects. Now I am speaking for myself. There is much more still to be learned. We have a great deal of data from animal experimentation. We have in addition much data on the effect of radiation on man derived from a number of different sources. These are perhaps worth mentioning.

You have heard of the normal or background radiation to which all of us are subjected. We know that the human race not only has developed in background levels of radiation similar to those of Washington but in regions such as Denver where the radiation is greater. Thus, during 30 years in Washington, a person might receive on the average a total accumulated dose of about 3.1 roentgens. In Denver or other mountain regions, because of increased cosmic radiation, this background might go as high as 5.5 roentgens.

In India a large population has lived for many centuries in the state of Kerala on sandbanks containing monazite. Recent studies of the radiation in this area have shown it to be up to 5 or even 50 times normal background. This population will be studied very carefully medically, but it is of interest that this relatively high level of radiation has not been sufficiently obviously detrimental to the population as a whole to cause abandonment of the region. However, one cannot say what the effects have been until very careful studies have been carried out.

The misfortune of men and women in the past has been wisely utilized by scientists to gain information as to the acute and chronic effects of radiation, and we actually have, as you have heard from the

experts testifying today, a large body of information as to what occurs in man.

To review briefly, we have data on acute exposures at varying levels of radiation from Hiroshima and Nagasaki. The studies on the degree of shielding from radiation afforded by structures in which the survivors were at the time of explosion are now being carried out and will greatly sharpen the information that we now have.

We have data on acute radiation exposure from those involved in the Los Alamos accidents and the minor accident at the Argonne. Some acute radiation from the shorter lived radioactive components of fallout of the close-in type was received by the crew of the Japanese fishing vessel and the Marshallese Islanders in 1954.

Data on chronic radiation in humans derives from the early workers with X-rays and radium as well as from radiologists up to the present day. Also, a considerable body of information has been gathered from patients treated for one or another disease with radioactive isotopes, radium or X-rays.

In general, we know that exposure to acute whole body external radiation will produce death for 50 percent of those receiving about 400 to 600 r.

Second, a single dose of radiation produces life shortening at significant levels. Human beings are too variable in their responses to radiation and in their state of health to permit any direct correlation, but it is probable that an acute dose of about 300 r. or repeated small doses totaling 2 to 3 times that would produce up to 5 years' shortening of life span. It will produce an increased incidence of leukemia. At present the rate of leukemia for the few most heavily exposed survivors at Hiroshima is about 1.3 percent. Radiologists, some of whom have received chronic irradiation on the order of 1,000 r. have 7 to 10 times as much leukemia as has the general population.

If there is a large neutron component in the initial acute exposure to radiation the likelihood of development of cataract is increased.

Radiation, whether acute or chronic, has a definitely damaging hereditary effect, because, in contrast to most cells of our bodies, there is no threshold for damage to the hereditary material and there is no recovery from injury in them. In chronic radiation, this is an important difference between the effects on most cells of a person's body and the effects on his germ cells. Since there is an appreciable power of repair possible in the body cells a higher dose is required to damage them seriously than is required to damage the hereditary material that perpetuates the race.

With acute or chronic radiation there is what is called a threshold effect in body cells. In other words, because many cells can continue to function even though irradiated and many cells in the body can be repaired even though damaged, we find that at low levels of radiation there is no observable effect.

This morning you heard mention of Senator Anderson's wristwatch. My own wristwatch has a luminous dial, and I measured the radiation from this on the back of the watch, putting the measuring device in the position of the skin on the back of my wrist. Assuming that I wore this 12 hours every day—actually I wear it a little more—the skin on the back of my wrist would receive 10 milli-r, or ten-thousandths of an r, and has been receiving it for close to 20 years. Yet this skin is just as normal as is the adjoining skin. That is, I feel

there is a definite threshold effect, and that until this threshold effect is exceeded, I am not going to stop a radioactive wristwatch.

This power of the body to repair itself, other than the hereditary material, has important bearing on the amount of radiation that man can withstand without demonstrable evidence of harm.

The present rate of testing of atomic weapons is such that the radiation from worldwide fallout is appreciably less than the background radiation. From the standpoint of heredity we should watch closely the levels of radiation.

The National Academy of Sciences report on radiation indicates that the doubling dose for mutations probably is in the range of 30 to 80 r, but may be as low as 10 r; it has been suggested that it could possibly go even as low as 5. Many geneticists believe that 30 to 50 r may be the doubling dose.

Representative COLE. Would you explain what you mean by a dou bling dose for mutations?

Dr. WARREN. Yes. There are a certain number of mutations that occur in the race quite naturally at the present time. You have heard of infants that have been born with imperfectly formed digestive tracts, for example. You have seen people who have 1 blue eye and 1 brown eye. These are the extremes of the sorts of mutations, some insignificant and some significant. We have hundreds of thousands of genes, and a change, a mutation in any one of these will produce changes under appropriate circumstances in the cells that are derived wholly or in part from that.

Senator JACKSON. Mr. Chairman—at that point, how can you tell whether it is due to the inevitable process of genetics and how can you tell when it is due to outside influence? How can you trace it?

Dr. WARREN. Only by very careful experimentation. These estimates are based on the best experimental data that we have available at the present time. There is some evidence derived from the eighty-thousand-odd births that have been studied in Hiroshima and Nagasaki as well.

So I would rather not answer that question in detail, because there are others who are geneticists who will be speaking. But in general I feel that we have reasonably sound foundations to emphasize that probably 30 to 80 r is a pretty good estimate for a level of radiation that will bring about twice as many mutations as now occur in the population.

Senator JACKSON. But all mutations are not due to radiation.

Dr. WARREN. No, indeed; not all congenital effects are due to mutations. For example, mutations can be simulated very closely by injury done to a fetus in utero, if the mother has had an attack of German measles or certain of the other types of virus diseases.

Senator JACKSON. While you do not want to go into this, I take it, because this is more a problem for the geneticists, you feel that they can tag and differentiate between mutations that are a natural result—the inevitable mathematical conclusion out of so many births—and mutations due to the outside influence of radiation?

Dr. WARREN. Yes. There is a very large-scale experiment that Dr. Russell, who is carrying on that experiment at Oak Ridge, will go into for you in the course of these hearings.

Senator JACKSON. I think it would be very important because this goes to the heart of the problem and unless you can tag them and

associate them with the problem that we are reviewing here, it would not be meaningful.

Dr. WARREN. Yes. Although not a geneticist, but as a scientist I am firmly convinced that radiation will produce mutations. The estimates that have been made by the majority of geneticists appeal to me as reasonable and sound estimates.

Senator JACKSON. In that connection, Dr. Warren, have there been and studies made of the situation as in Denver where people live at 5,000 feet as distinguished from people living at sea level? I was told that these mutations do not occur as anticipated.

Dr. WARREN. One would have to get a much higher level than occurs in Denver to reach the doubling dose that we have spoken of.

Senator JACKSON. What about in the Andes?

Dr. WARREN. The difficulty in the Andes—I have been at Moracoacha and a number of the other high altitude villages in the Andes—is that the population there is so short lived from other causes—public health is so poor—that it is very difficult to get any satisfactory statistics. I think that we can hope to get much more valuable data from the studies in the monazite areas and these studies are being carried forward by the Indian Government at the present time.

Representative HOLIFIELD. Of course, the length of life in India is much shorter than it is here.

Dr. WARREN. That is quite true.

Representative HOLIFIELD. There are a lot of factors that might enter into it, and not only the comparison of their longevity and ours, but also there would have to be a comparison of the average length of life in India, and those who live on these monazite sands.

Dr. WARREN. Very fortunately there is a very similar population of the same ethnic character and the same social status who live about 10 to 20 miles away. There has been no significant intermarriage between the two groups. So we hope that the Indian Government will have a good built-in control.

I have been speaking of this possible level of the doubling dose of 30 to 50 r. Since there is uncertainty in these figures and since many years of observations will have to be made before they can be firmed up we should take no chances but use a conservative figure such as 10 r for all types of added radiation, of which medical diagnostic X-rays will use a portion.

Representative HOLIFIELD. At this time, in order to get a realization of what a chest X-ray would expose a person to, how many roentgens would you say a person would receive from a chest lung X-ray?

Dr. WARREN. This would depend on the type of X-ray, Mr. Holifield. If it were one of the photoroentgen type, it would be higher than a full chest. We are speaking here not of the direct X-ray, but the scatter from that direct X-ray to the gonads. You heard this morning from a very competent radiologist, Dr. Friedell, and since he is still in the room, I believe, I wonder if he could tell you what he uses. That would make the point even stronger and more real.

Representative HOLIFIELD. Dr. Friedell, I suggest that you come forward. You do not need to leave your chair, sir.

My question, to make it more direct, would be this: What would be the exposure of a chest X-ray—as long as you are here, I will add another—and a fluoroscoping examination of the chest, and what would be the scatter to the gonads?

Dr. FRIEDELL. I am glad you make this distinction. First of all, there is a difference between radiation on the thorax and radiation to the gonads. The radiation to the thorax is considerably larger than to the gonads. As Dr. Warren pointed out, that makes a difference whether you have the miniature kind of chest examination which is really a photograph of a fluoroscopic image or whether you have an ordinary X-ray film that many of you have had for various studies.

Somewhere of the order of six hundredths to one tenth of a roentgen is given to the thorax for an exposure to get a satisfactory chest film. Depending on the various methods that are used for protection of the gonads and the possible protective devices which may be placed over the gonads, the dose to the gonads is considerably reduced. From the scatter alone, it may be as low as one one-hundredth of the dose given to the thorax. I would not want to put a firm figure on it because it is a function of how it is done.

From the point of view of fluoroscopy, there is not any comparison between the amount of radiation delivered to the chest and to the gonads, because of scatter when fluoroscopy is used, because at the present time the fluoroscopic methods require a large dose of radiation to be visible on the fluoroscopic screen. Depending on the time, I would say that a chest could easily receive as much as 5 to 15 roentgens in one examination.

Representative HOLIFIELD. In the case of exploring for a swallowed safety pin by a child, for instance, where you have to probe with instruments, and you follow it with your fluoroscope, what would be the exposure?

Dr. FRIEDELL. That is difficult to estimate, but I think this would help you. Most fluoroscopic machines will turn out somewhere in the order of 5 to 10 roentgens a minute. Some will turn out much more, but they are not really carefully controlled. Generally the lower limit is about 5 roentgens a minute. This determines in effect how much radiation will be received by the body in general, and is generally fairly easy to calculate what might be received by the gonads. If the radiation is directed to the gonads for various reasons, they receive much more.

Representative HOLIFIELD. Do you think there is a comprehension on the part of most radiologists of the importance of the damaging effects of this scatter from a genetics standpoint?

Dr. FRIEDELL. I think this is a difficult question for me to answer. I know that people in whose circle I move are very concerned with the problem and are examining it very carefully. I would say that the radiologists in general are now very acutely aware of this problem. It is conceivable that they were not aware of it 10 or 15 years ago, and are now beginning to institute all the necessary measures to get as much protection as we can.

Representative HOLIFIELD. Certainly when they are utilizing a machine with such potentially damaging effects, they should from a professional standpoint guard the people as much as possible.

Dr. FRIEDELL. I think I would agree with this, but I would also like to add to this that you are always faced with the problem of measuring the value of this medically as compared with the possible hazard that is introduced. This is a very difficult thing to measure sometimes. It is conceivable that much error can be introduced, but

I think that most physicians are acutely aware of weighing these two things and must do the best for the patient.

Senator HICKENLOOPER. I would like to ask Dr. Friedell or Dr. Warren a question or two.

I wonder if you ever knew Dr. Erskine?

Dr. FRIEDELL. Yes, in Iowa.

Senator HICKENLOOPER. He was an old friend of mine who died a few years ago. He died without doubt from radiation which he got in the early days from his experimental work. He did some pioneering work, especially on the mechanics of measurement of radiation in those days.

The question I want to ask is somewhat along the line of Congressman Holifield's question. From a statistical standpoint, I think manifestly years ago—20, 30, 40 years ago—when the average small or large town physician's office did not seem complete unless he bought an X-ray machine, and without doubt used it with great frequency without realizing the potentials of this machine, without the ability to measure quantities or absorption or anything of that kind, and with little or no schooling in it, I wonder if there is any statistical background that would tell us how many cases of leukemia or perhaps induced cancer or something of that kind might have occurred in the American population during those periods when there was very little appreciated as to the long range possible effects of radiation of this kind.

Dr. WARREN. I think I might be able to answer, if I might, Senator Hickenlooper.

Senator HICKENLOOPER. Yes.

Dr. WARREN. I had been interested in the problem of the life span of both radiologists, general practitioners and certain specialists. We find that the life span of the general practitioner is not significantly at variance with the life span of white males over 25 in the United States. The average doctor starts his practice somewhat around 25 years of age, so that is what we took.

This means, then, that the average doctor, not a specialist in radiation or not in the specialties using radiation a great deal, such as orthopedic surgery, urology and some of the other specialties, has about the same life span. There is evidence that he has slightly more leukemia, but not as much as the radiologist who has 7 to 10 times as much as the males in the general population. He has possibly half again as much. It is rather hard to pin it down exactly.

I think it should be remembered that there are relatively few of the general practitioners who used their X-ray machines all day long. They would use them from time to time on their patients, and had appreciable rest periods during which their body cells could recover from the radiation injury done.

Senator HICKENLOOPER. I either heard or read some testimony with respect to the data on physicians, but the real point of my question I was directing at the use of X-ray in treatment years ago on patients when the effects of those X-rays were not so well known, and there was a period of time some years ago when it was really quite widespread, and there is no telling what the strength of the treatment would be that many patients received at that time. I wonder if there would be any statistical data that could indicate malignancies of various types from that treatment, rather than from natural causes.

Dr. WARREN. You saw on the chart an estimate as to X-rayed adults here. I think that the best data on this are the group with so-called ankylosis spondylitis—a form of arthritis of the spine—an X-ray treatment gives some relief to the pain and may help the course of the disease somewhat. A group under the direction of Dr. Court Brown in England studied this very carefully. I have here the white paper on radiation effects issued by the United Kingdom approximately a year ago. It gives an indication that the dose ranges ran from as little as 500 *r*, or possibly a little under that to the spine, up to more than 2,750 *r*; that this caused an increase in the crude incidence of leukemia—these are uncorrected figures—ranging from 4.1 per 10,000 people treated at the lower dose level, or 2.2—which might be sheer chance, at less than 500 *r*—up to 17.6. So arguing from this, I think it might be said that there were probably a scattering of cases of leukemia induced in the way you spoke of.

Senator HICKENLOOPER. Would you have an estimate at this time as to how long a period of time it has been since you feel that you can have some reliable data on leukemia, and many other ailments which people undoubtedly had many years ago, but which were not diagnosed by the physicians? I remember when they used to say people died of acute inflammation of the bowels, when it was probably a burst appendix, and that sort of thing.

Dr. WARREN. Yes. I think you pointed out a very important thing, Senator Hickenlooper, that medical diagnosis is steadily improving. I think in certain areas of the country in the larger medical centers, leukemia has been pretty well recognized from 1930 on; for the bulk of the country, leukemia has been very well recognized from 1945 on. I think our statistics from 1900 to 1910 may have caught perhaps half of the leukemia cases or something of that order. This is only a wild estimate, however.

Senator HICKENLOOPER. Thank you very much.

Representative HOLIFIELD. Thank you very much. You may proceed with your statement.

Dr. WARREN. At present the rate of radiation from fallout gives a probable 30-year dose of 0.1 roentgen. The data on chronic radiation to our bodies and those of animals indicates that rather more than the acute lethal dose of radiation can be withstood, though not without harm, if it is given over a protracted period of time. The effect of protracted radiation may be half or less as great as radiation given at a single time. If significant damage is done to body cells there is never complete repair, but rather atrophy persists and eventually cancer may develop.

The ill effects known to come from chronic radiation, are, as you have heard, damage to various body tissues ranging from the destruction of cells to undue or cancerous proliferation of cells. Thus, in the skin of the early radiologists, we saw atrophy occur, finally ulceration, and in some instances even skin cancer. The blood responds at first to radiation at low levels by minute and insignificant changes in some cells. For example, the lymphocytes may show a rare cell with double nuclei, the meaning of which has not yet been established. Continued exposure to radiation leads in some people to the failure of formation of adequate blood cells condition known as anemia or agranulocytosis, or, at times, to an overly enthusiastic reparative response which leads to the development of leukemia. Chronic exposure

from radium, particularly radium absorbed internally, has been shown to be injurious and radiation changes in bone can be detected with levels of radium in bone as determined years afterwards on the order of 1 microgram. Of course, these levels were initially appreciably higher.

Since one of the radioactive fission products, strontium 90, is deposited in bone, there is much concern to advance our knowledge of radioactive strontium, the amount that enters our bones, and the effect that it may have there. Strontium 90, at fallout levels or at levels many times higher, has no significant genetic effect. Neither is there firm evidence that it has a leukemia producing effect. If we assume that the radiation effect from strontium 90 or from other sources has no threshold (and this assumption is contrary to most existing information with regard to somatic effect) if we assume this, I say, it would follow that there would be a small statistical increase in bone tumors. I doubt very much that it would cause any increase in leukemia. It is striking that in those persons who have had radium deposited in their bones there has been no evidence of leukemia, even though they have developed bone sarcoma. The evidence for the possible development of leukemia from strontium 90 rests on mice treated with radioactive strontium that showed leukemia. However, leukemia is so common a disease spontaneously in mice that I hesitate to accept this observation as contradicting the information we have from experience with humans and with a number of animal experiments at the present time.

Let us, however, make the worst assumption, that there is no threshold and that we might be concerned with a linear increase in both leukemia and bone sarcoma. On this basis, as you have heard, the average level to be expected from uptake of strontium 90 already produced by weapons testing may be about five so-called sunshine units. While there is no evidence that even 10 times this level is harmful, if we assume that there is no threshold, I would be reluctant to see the average strontium 90 content of bones, particularly in children, go much above 10 times the present level. It is possible that additional experimental work will enable us to go safely beyond this tenfold increase.

Representative HOLIFIELD. Thank you very much, Dr. Warren.

Senator Jackson, do you have any questions?

Senator JACKSON. I have no further questions. I am very happy to see Dr. Warren back with us. We are very proud of his great contribution while he served as Director of the Division of Biology and Medicine of the Atomic Energy Commission.

Dr. WARREN. Thank you very much, Senator Jackson.

Representative HOLIFIELD. Dr. Warren, will you be back with us in a few minutes for our discussion period?

Dr. WARREN. Thank you.

Representative HOLIFIELD. At this point I would like to say that it is my understanding that Dr. L. H. Hempelmann, of the University of Rochester, Strong Memorial Hospital, will deliver a paper in Pittsburgh on June 11, called Irradiation-Induced Cancer in Man. When we receive a copy of this paper I would like to insert it into the record at this point.

(The material referred to follows:)

IRRADIATION-INDUCED CANCER IN MAN

L. H. Hempelmann

The possible development of cancer, and this includes leukemia, is an occupational hazard known to persons working with X-rays or nuclear radiation. Recently, this type of radiation carcinogenesis has become a matter of increasing concern to the scientific world and to the world at large. There are several reasons for this. The first is the exposure of ever increasing numbers of people to man-made radiation. (This includes not only persons working in the field of atomic energy, but also people receiving the benefits of Western-style medicine, and indeed the entire world population now that the radioactive fallout from the hydrogen bomb test programs is worldwide.) The second reason for concern is in the observation that the radiation doses necessary to induce cancer are smaller than they were believed to be formerly. The third reason for the current interest in radiation carcinogenesis is the recent evidence which challenges the concept that all somatic effects of radiation are threshold reactions.

For more than 50 years, it has been known that X-rays and gamma rays can cause cancer. The first case of skin cancer in an X-ray worker was reported in 1902. Gamma rays were the first carcinogenic agent used in the laboratory to produce experimental cancer in animals. In the past half century, the literature concerned with radiation-induced cancers has become voluminous. Review of the literature shows that almost any tissue of the body will undergo malignant change under proper conditions of exposure. In most instances, these exposure conditions involve repeated or chonic irradiation of a small volume of tissue with doses totaling several thousand roentgens. This is not the kind of radiation-carcinogenesis I will consider today. Instead I will confine my attention to the incidence of malignant disease in four human populations in which the total body of each individual, or at least a substantial portion of the body, was exposed to ionizing radiation. I will also mention a retrospective study in which the history of previous radiation exposure has been determined for a group of children with leukemia and other forms of cancer.

The first group of exposed individuals in whom the incidence of malignancy has been studied is composed of the radiologists. Since the first recorded case of leukemia in a radiologist in 1912, it has been suspected that there might be an association between this disease and prior radiation exposure. This suspicion was supported by experiments in animals which showed that leukemia could be produced by irradiation with X-rays. In 1942, Henshaw and Hawkins made a systematic study of the causes of death in physicians. They observed that the incidence of leukemia in physicians was slightly higher than it was in the general male population. Several surveys have been carried out since this time to determine the incidence of leukemia in radiologists. Probably the best figure illustrating the increased leukemia rate is that of E. B. Lewis who has calculated the age-specific death rate from leukemia for radiologists and for the adult male population. He estimates that the death rate from leukemia in radiologists is approximately eight times the expected rate for the general male population. While this figure of eight-times-normal is strikingly high, it is important to emphasize the fact that leukemia is a rare disease and that the actual number of people who contract it, even among the radiologists, is not great. Up to 1948, only 37 cases of leukemia were reported in the medical literature among the thousands of people who had worked with X-rays during the preceding 50 years. I should also like to mention the fact that the cases of leukemia usually occurred late in the life of the radiologist. The average age of death of all radiologists dying from leukemia was almost 59 years. This is essentially the same as the 60-year average age at death from all causes. I should like to emphasize the fact that aside from leukemia and skin cancers, the incidence of other forms of interval cancer in radiologists is not increased. Incidentally, I should like to point out that the exposure of the radiologists is partial body rather than total body and is protracted over a period of many years.

The second group showing an association between leukemia and radiation exposure is the Japanese people exposed to the radiations from the nuclear detona-

tions in 1945. Table 1 shows how the incidence of leukemia can be correlated with the distance of the exposed individuals from the hypocenter under the explosion. In the last column, you can see the ratio between the observed and expected incidence of leukemia. With regard to the interpretation of these data, I would like to point out that the irradiation of these individuals, unlike that of the radiologists, usually involved exposure of the entire body to a single dose of mixed irradiation, primarily consisting of gamma rays. Dosage data are uncertain but the dose certainly falls off with increasing distance from the hypocenter. The latest unclassified figures that I have seen indicate that the mean dose for each of the exposure zones is 1,500 rem for the first zone, 500 for the second and 50 for the third. These are not firm figures and do not take shielding among other factors into account. To show how uncertain they are, I would like to point out that almost all the cases of leukemia occurring in persons in the 1,500 to 1,999 meter zone had severe radiation complaints; it is difficult for me to believe that they did not receive considerably more than 50 rem.

TABLE 1.—*W. M. Court Brown, R. Doll, Hazards of Nuclear and Allied Radiations (table 2A, p. 85): A comparison between the observed and the expected incidence of leukemia among survivors of the Hiroshima atomic bomb explosion exposed at various distances from the hypocenter; persons subsequently resident in Hiroshima City only*

Distance from hypocenter at time of explosion (m.)	Number of cases with onset in the 8-year period 1947–54		Number of deaths expected among the survivors in an 8-year period [1]	Ratio of total cases observed to expected
	Confirmed	Suspected		
Less than 1,000	15	0	0.15	100.0 : 1
1,000 to 1,499	28	1	1.32	22.0 : 1
1,500 to 1,999	6	1	2.33	2.6 : 1
2,000 to 2,999	6	0	3.96	1.5 : 1
3,000 or more	4	2	4.83	1.2 : 1
All distances	[2] 59	4	12.59	4.7 : 1

[1] Calculated from the Japanese mortality data for 1952. In calculating the numbers of expected deaths, certain assumptions had to be made about the rate of change of the numbers of survivors in the different age groups, and the figures must be regarded as approximate estimates.

[2] Two cases referred to in table 1A are omitted, since the onset of symptoms in one patient was in 1955 and in another patient, who died in April 1955, the date of onset is unknown; the latter patient was exposed at a distance of 2,400 meters from the hypocenter.

The third exposed population is a series of patients with a severe form of rheumatic disease of the spine known as ankylosing spondylitis. This is a painful, crippling disease occurring mainly in young men. Intensive X-ray therapy has often been used with considerable success in treating this illness. X-ray doses of 2,000 r. given to the entire spinal column through ports 10 cms. wide are not unusual. Such treatments are not given all at once but are usually fractionated over a period of weeks. Such a series of treatments is often repeated once and possibly twice. In a group of 15,000 patients in Great Britain, the incidence of leukemia has been determined. Table 2 shows how the 37 cases found in this group were distributed according to the total dose administered to the bone marrow. These data show a linear relationship between leukemia rate and dosage. If we extrapolate to the lower dose range, it is observed that the dose of radiation to the spine necessary to double the incidence of leukemia is of the order of 100 roentgens. If the dosage data is expressed not in terms of roentgens to the bone marrow but, rather, in terms of megagram-roentgens to the body, the relationship between dose and incidence is curvilinear rather than linear. One criticism usually directed at this type of clinical studies on X-ray therapy patients is the lack of a really good control group with which to compare the treated patients. The British were able to collect as controls only 400 patients with spondylitis not treated by X-rays. Another criticism that I would like to point out is the small number of cases in the low-dose range, only 2 cases of leukemia having occurred in patients receiving less than 500 r. to the spine.

TABLE 2.—*W. M. Court Brown, R. Doll, Hazards of Nuclear and Allied Radiations (table 2B, p. 89): The numbers of male patients developing leukemia and the crude incidence rates after different doses of radiation (measured by the maximum amount received at a point in the spinal marrow)*

	Amount of treatment, maximum dose to the spinal marrow (r.)						
	0	Less than 500	500 to 969	1,000 to 1,499	1,500 to 1,999	2,000 to 2,749	2,750 or more
Number of men developing leukemia	----------	2	8	8	8	6	5
Crude incidence per 10,000 men per year	[1] 0·5	2·2	4·1	4·2	11·3	13·0	17·6

[1] The rate given for "no treatment" has been estimated from the national vital statistics for all forms of leukemia, and weighted to allow for the fact that not all the patients in the series were certified as dying from leukemia. If lymphatic leukemia is excluded (as may be more appropriate) the rate is 0·3.

The fourth population I would like to discuss consists of 1,700 children treated with X-rays in infancy. They were treated for a condition known as enlargement of the thymus gland which in the past has been alleged to be associated with sudden death of a previously healthy child or with severe and sometimes fatal respiratory distress in young children. When a diagnosis of thymic enlargement was made in a sick child, it was customary to treat the child with a beam of X-rays to the region of the chest. In the 1920's and 1930's, doses of 500 or 600 roentgens or more have frequently been administered through ports which covered the entire chest of the child. Fear of the consequences of thymic enlargement became so intense that asymptomatic children who were suspected of having this condition were often given prophylactic X-ray treatment to prevent symptoms. In one city in upstate New York it has been found that approximately 1 percent of the children born between 1925 and 1950 have been treated with X-rays for thymic enlargement. This form of treatment is still used at the present time but the practice is less common and the port size is considerably smaller now.

Table 3 shows a comparison of the observed and expected incidence of cancer in children given X-ray treatment for thymic enlargement. You can see that whereas 2.6 cases of cancer would be expected to occur in a normal group of children of this size and age distribution, 17 or probably 19 were found; 0.6 of a case of leukemia should have occurred but instead 7 or probably 8 have been found. The most striking increase of all is found in the case of thyroid cancer where 0.09 case was expected and 6, or more recently 10, cases have been observed. Now as controls we have 2,000 untreated siblings of the children which, I admit, are not good controls. Nevertheless, they have 5 cases of cancer rather than the 2.7 expected cases and no cases of leukemia or thyroid cancer. (It does seem clear that this group of children with thymic enlargement treated with X-rays has an increased incidence of cancer.) Table 4 illustrates how these cases of malignant disease were distributed among the children who received more or less than 200 roentgens. In the case of leukemia, you can see that there were 2 cases among the 600 children receiving less than 200 roentgens and 5 cases among the 800 receiving more than 200 r. Although the number of cases is small, it seems likely that there is a relationship between the size of the dose and leukemia incidence. No other cases of cancer, however, were observed in children receiving less than 200 r.

TABLE 3.—*Expected and observed rates for malignant neoplasia* [1]

	Treated children		Untreated siblings	
	Expected	Observed	Expected	Observed
All cancers	2.6	17 (?19)	2.7	5
Leukemia	.6	7 (?8)	.6	0
Thyroid cancer	.08	6	.08	0

[1] From study by Simpson, Hempelmann, and Fuller on 1,722 children treated with X-rays for thymic enlargement from 1926 to 1951.

TABLE 4.—*Distribution of neoplasia according to amount of radiation*[1]

	Under 200 r.	Over 200 r.	Unknown
Number treated	604	804	313
Cases of leukemia	2	5	(?1)
Other cancers	0	4	0
Carcinoma of thyroid	0	6	0
Adenoma of thyroid	0	6	3

[1] From study by Simpson, Hempelmann, and Fuller on 1,722 children treated with X-rays for thymic enlargement from 1926 to 1951.

The last study that I would like to mention is a so-called retrospective study of the history of previous X-ray exposure of 547 British children who died before the age of 10 from leukemia and other forms of cancer. The controls in this study consisted of the best friend of the child at the time of his death. Information was obtained from the parents as to exposure of the mother as well as the child and table 5 shows the information so obtained. I will mention the only category in which a significant difference was found in the history of X-ray exposure of the two groups of children. This category involved X-ray examination of the abdomen of the child's mother during pregnancy and this is seen in the first row of figures. You can see that whereas only 24 mothers of the control children had this form of examination, 42 or almost twice as many mothers with children with leukemia were examined in this way. This is 42 out of 269. A comparable difference also hold the exposure of the mothers of children with other forms of cancer and of the control children. There were 21 such examinations in the controls and 43 in the mothers of children with cancer. Now if you assume a cause-and-effect relationship here, you can see that all cases of childhood leukemia in this series cannot be explained on the basis of X-ray exposure of the fetus. Only about 8 percent of the total cases had this type of X-ray exposure. I would like to point out here that the doses involved in this type of X-ray examination are small. The fetus received about 2 roentgens per X-ray film and usually 4 to 6 films were taken per examination.

TABLE 5.—*Lancet, Sept. 1, 1956: Past histories*[1] *of X-ray examinations and antibiotics in 547 children with malignant disease and 547 controls matched for age, sex, and locality*

Number of mothers and children X-rayed		Leukemia		Other malignant diseases		All malignant diseases	
Period	Type of exposure	269 cases	269 controls	278 cases	278 controls	547 cases	547 controls
Antenatal	Diagnostic:						
	Abdomen	42	24	43	21	85	45
	Other	25	23	33	32	58	55
Before conception of survey child	Therapeutic	------	------	------	1	------	1
	Diagnostic:						
	Abdomen	17	24	28	30	45	54
	Other	103	88	108	119	211	207
Postnatal (children only)	Therapeutic	1	------	1	------	2	------
	Diagnostic	45	49	46	50	91	99
	Shoe fittings	55	52	40	46	95	98
Total number of mothers[2]		140	130	160	154	300	284
Total number of children		89	91	75	84	164	175
Either mother or child, X-rayed		179	172	194	198	373	370
Postnatal medication (children):							
Sulfonamides		51	45	42	42	93	87
Antibiotics		68	52	50	58	118	110

[1] I. e., before the onset of the fatal illness in the affected child or equivalent period in the control child.
[2] Since a mother or child may appear in more than 1 X-ray category, the totals in this category are less than the sum of totals in the 3 preceding ones.

In summary, I would like to show (table 6) a recent paper published in Science by E. B. Lewis, on the relationship between leukemia and radiation exposure. He has taken the data from the first four surveys that I discussed and has calculated the probability of any single individual developing leukemia per rad absorbed in the bone marrow. The figures in the last column give his best estimate of probability turn out to be $1-2\times10^{-6}$ per year. It could be chance, of course, that these calculations turn out to be so close, and it must be admitted that the dosage data in the first two groups are not accurately known. If it is not coincidence that these probabilities are practically identical, then the data suggest that the amount of blood-forming tissue exposed and the time during which the exposure takes place are not matters of great importance in the induction of leukemia. In this respect, then, the leukemogenic effect of radiation would seem to be cumulative.

In conclusion, I would like to say that the data obtained from surveys of exposed human populations indicate that there is a clear association between leukemia and previous radiation exposure. The incidence of cancer, particularly thyroid cancer, may be increased in children irradiated before or after birth. But there is no evidence that other forms of cancer are more frequent in adult populations exposed to total body radiation. In the case of leukemia there seems to be a definite relationship between the incidence of the disease and the dose of radiation provided the exposures are high. The data at hand is insufficient to allow us to conclude that this relationship also holds for low-dose levels. I would like to emphasize the fact that the risk of any given individual developing leukemia is small even if he has received considerable exposure, but when large populations are involved the absolute number of people affected may be large.

TABLE 6.—*E. B. Lewis, Science: Summary of the estimates of the probability of radiation-induced leukemia per individual per rad per year*

Source of estimate	Type of radiation	Region irradiated	Types of leukemia produced	Probability of leukemia of specified type per individual per rad (or rem) to region irradiated per year		
				Estimated range		Best estimate
				Lower limit	Upper limit	
Atom-bomb survivors	Gamma rays plus neutrons	Whole body	All	0.7×10^{-6}	3×10^{-6}	2×10^{-6}
Ankylosing spondylitis patients	X-rays	Spine	Granulocytic (only?)	0.6×10^{-6}	2×10^{-6}	1×10^{-6}
Thymic enlargement patients	do	Chest	Lymphocytic (only?)	0.4×10^{-6}	6×10^{-6}	1×10^{-6}
Radiologists	X-rays, radium, etc	Partial to whole body	All (?)	0.4×10^{-6}	11×10^{-6}	2×10^{-6}
Spontaneous incidence of leukemia (Brooklyn, N. Y.).	All natural background sources	Whole body	do		10×10^{-6}	2×10^{-6}

Representative HOLIFIELD. In the meantime the staff has made arrangements for Dr. Ernest Pollard of Yale University to speak now instead of tomorrow.

Proceed, please, Dr. Pollard.

STATEMENT OF DR. ERNEST POLLARD, BIOPHYSICS DEPARTMENT, YALE UNIVERSITY [3]

Dr. POLLARD. Thank you. As a professor, I am a little panicky away from the blackboard, so may I use it?

Representative HOLIFIELD. You certainly may.

Dr. POLLARD. Mr. Chairman, I am appreciative of the privilege of being able to testify before this committee. I think I should first of all give an indication of my field of competence, because since I have never worked on anything larger than a bacterium, and this is approximately one million millionth of the size of a human being, it might very well be questioned as to whether I have any right to come up here at all. I am a biophysicist, which means I need to know biology and physics. I am one of the very small number of the nuclear physicists who at the time of the explosion of the atom bomb decided to do something about living things. I have devoted my study to biology since 1947, and in particular I and a very strong group that work for me, have been trying to find out the fundamental nature of the action of radiation on living things.

One must realize that there is throughout biology a considerable similarity. The same molecules which are concerned with animal cells are also concerned with plant and bacterial cells. We do learn the fact that there is a great importance to these large molecules, and this brings me perhaps to the first point I would like to make and that is that we really do need a much more fundamental understanding of biology.

If I might, without showing disrespect, make a short remark about the difference between physics and biology; in our atomic energy establishments great attention is paid to fundamental physics. There must be at least $25 million a year going into research on high energy machines. These are not related to the immediate problem of nuclear energy at all. They are very definitely of an esoteric character concerned with high energy problems. There is no analogy in biology.

[3] Professor of biophysics and chairman of the department of biophysics at Yale, is one of the Nation's outstanding scientists in this relatively new field of biophysics. Under a $3 million grant from the John A. Hartford Foundation, the new department of biophysics at Yale, under Professor Pollard's direction, will apply the methods of atomic and nuclear physics to a purely humanitarian and constructive end. For example, Professor Pollard is using a cyclotron to study disease-producing viruses. The son of Emma H. and the late Samuel Pollard, the Yale professor was born in Chaotong Fu Yunnan, China, where his father was a missionary for the British Methodists. He received his B. A. degree from Caius College (Cambridge, England) in 1928, and his Ph. D. in 1932 from Cavendish Laboratory at Cambridge. He was an assistant lecturer at Leeds University in England from 1930 to 1933, when he came to Yale as a Sterling Fellow. He was appointed an instructor in physics at Yale in 1936, was named an assistant professor in 1939, an associate professor in 1942, and was promoted to the rank of professor in 1950. He was chairman of Yale's biophysics committee from 1946 until 1955, when he was named chairman of the department of biophysics. Mr. Pollard helped design and build Yale's first atom-smashing cyclotron in 1939. During World War II he worked on radar problems at the radiation laboratory of the Massachusetts Institute of Technology. For his research, which was instrumental in establishing radar systems in Europe and the Pacific to detect the approach of enemy planes and to guide lost Allied aircraft back to their home bases, he was awarded a Presidential Certificate of Merit. He is the author of Applied Nuclear Physics, published originally in 1942 and again in a second edition in 1949. He also is the author of Microwaves and Radar Electronics (1947); Physics of Viruses (1953); and of numerous papers published in scientific and technical journals. From 1951 to 1954 he was a member of the Scientific Advisory Board to the U. S. Air Force. (Submitted by witness.)

There we could use the fundamental biological research, and it would be a fine thing to see this disparity removed. I think it could be removed in part within the atomic energy operations. I do need to say that.

The nature of radiation action is worth a moment's thought. It is very energetic. I could not help wondering whether an analogy to the question as to whether there be a threshold effect would not be something like this. If you notice that a thousand shafts of lightning knock down a thousand trees in a town whether you would argue that one shaft of lightning would knock down one tree. I cannot help thinking that there is something like that. The energy released by ionizing energy is enormous, far in excess of any chemical process, in excess by a factor of between 10 and 100 always.

In view of this very energetic release, the large molecules which are very important in biology, are inactivated. We have in our group studied over 30 of these since the war, and as for the cases where we observed a recovery of the actual effect which is received from the radiation damage, I cannot recall one such case occurring.

When we say there is recovery—unquestionably there is no doubt that a human being irradiated does recover—he is calling up either some other mechanism in a cell or he is calling on a new cell. The problem we have really to ask ourselves is, therefore, the question as to whether this recovery mechanism is going to be adequate for the rest of that person's life. Whether we are going to let the cell which has been damaged go through the 30 or so more divisions it may yet have to undergo in the lifetime of the person, and say we know it has recovered adequately, or whether we take a rather careful viewpoint on that, and say we are not so sure.

Representative HOLIFIELD. Are you talking about the somatic cells?

Dr. POLLARD. Yes; I am speaking about somatic cells. I believe the germ cells undergo forty-odd divisions, and a run-of-the-mill cell, not all—the peripheral cells in the skin are not going to be used any more—the ones that are deeper down will have to be used again, and a human lives a long time, and many divisions have to occur.

We are stating as an act of faith that when we say recovery is complete, that that recovery is adequate for something like 60 years, and many divisions. This is an act of faith which I as a biophysicst am not ready to undertake. I would definitely not want in the record any statement that I thought such recovery would last throughout the lifetime of an individual. I would prefer to be very much more conservative.

The energetic events that occur in the cell are very far apart anyway. If we take 100 r. as a dose, these events then occur on the average about as far apart as the cells are themselves far apart. So if we are saying that there is a threshold of an kind, what we are saying is that the events have to be close together. That is, 100 r. already has them far apart. If there is a threshold then the events must be close together. That is why there is a threshold. They must occur close together in time or in space. Even for 100 r. they are already far apart, or the order of distance apart of two cells. Therefore, we have a right to say that if 2 or more are needed in 1 cell, we would expect not a linear increase in radiation effect—we would never see a linear increase—we would always see an increase which would

look something like this. This is observed [drawing on the blackboard].

The effect would appear in this parabolic way showing a curve of this form. For the case of certain types of chromosome aberrations this is observed.

If we see something which looks like this, the tipoff is that it is aiming at a point out on the dose axis which does look like a threshold. If we do not see that, then I think we have to presume as a hypothesis to work on and guide ourselves that it will indeed go straight down and will be linear. If it looks like it is linear up high, the probability is that it is linear down low. It is a very strange thing to explain a curve of the following form (drawing). I know of no interpretation of a curve which is linear in the upper part and ceases to be linear below. It is very queer. I know nothing about fundamental radiology that leads me to expect an effect of that kind. So if I see a linear effect up high, then I suspect it is indeed linear all the way down.

I notice that the usual effect in a class is taking place and a little diversion will not be harmful. I have what is getting to be the trademark of the biophysicist. These are on the market now as poppet beads. I can represent here one form of the key molecules of biology. This is a molecule of nucleic acid. It occurs in a long chain and it is doubled. On this chain are different colored beads indicated. They are the markers which determine our heredity and combinations in some manner of these are responsible for what conditions the nature of a cell and its future existence will be.

What radiation can do is either break one of these in which case we have a partial chain, or it can break both. If both are broken, and this is a somewhat unusual event, and it may account for a little difference between cosmic rays and internally contained radiation, there is no simple agency of repair, not for a molecule. They may indeed repair and randomly perhaps they do. But if a break like this occurs and is perpetuated, then just as I will have trouble putting this back together—and I do not want to take the committee's time to do so—so will the cell have trouble putting it back together. The damage will therefore be in some measure permanent.

The lack of our seeing permanent damage is partly the lack of our knowledge today. We do not know how to look. I would like to make an analogy between a person whose car has a convoy run into the side of it and scratches the paint. I can easily see that the people in charge of the convoy might say that the motor is not affected and the tires are all right, but if he did not know about the phenomenon of the paint rusting, he would not come to accurate estimate of the damage to the owner. The owner might in fact have sustained considerable damage to the car.

It is the same today. We don't yet understand how the cell works and how it is tied into the whole body. In fact, in the things that concern degenerative disease, we have almost no knowledge. We have very good knowledge on communicable disease, but in degenerative disease we are not so sure. I would like to submit that radiation does produce a scratch, and it always produces a scratch, and it would be a conservative and wise thing to say that we were not sure whether that scratch were important or not, and to then treat it as though it was, because it might be like the paint on the automobile, it can run into a hundred dollars.

I have been asked by the committee to answer one specific question. This is the question as to whether radiation from materials such as strontium, which is inside the body, differs in any way from radiation which is outside, such as cosmic rays. I have put this to my group, and we have thought about it. It is a very difficult question. It is not a simple question to answer. I think for the guidance of the committee, I would like to give an answer as follows:

The only reason why the effect could be less would be that some radiation were buried in the bone, and it would have to be buried deep, and in a part that does not matter. I do not think that even bone can be considered as inert. Certainly if a bone breaks and heals, it means it is not inert. I would therefore be very surprised if there was ever any case in which internal radiation were less effective than external radiation. I would expect it by all likelihood to be the same.

There are, however, reasons that might make it more. If it should turn out, as been said by two people, Dr. Mazia and Dr. Steffensen, that calcium binds together the units of the chromosome and strontium could replace calcium, then indeed internal radiation of that type might be extremely effective.

Therefore, one might get a higher proportion.

Personally, I would be surprised if this effect exceeded 2, and I would be very surprised if it exceeded 10. I would suggest for a working operation for the committee that it treat external and internal radiation, as equal as regards its physics only—I am not speaking about whether irradiating the bone marrow or the bone is more important.

Specifically, for example, I would say that internal potassium which competes with strontium is probably far less effective and less dangerous because it is primarily in the muscle and the strontium is in the bone. I am not concerned with such matters of being near vulnerable material. I am speaking solely of the physical nature of the radiation. I would suggest that it be approximately the same. Thank you.

Representative HOLIFIELD. Thank you very much, Dr. Pollard. Are there any questions?

(A supplementary statement by Dr. Pollard follows:)

FIELD OF COMPETENCE

My field of competence has been (1) in the nature of the physical character of radiation in which I have worked since my graduation from Cambridge in 1928, (2) the action of radiation on large molecules, viruses and bacteria, a field in which I have worked since 1947 with the strong support of a group of able people, (3) in this work we have followed a fundamental approach aimed at the understanding of the basic character of radiation action.

RADIATION AND BIOLOGY

Understanding radiation action requires understanding of biology. It is here that we lack certainty and a large part of this lack is due to the low priority which has been accorded biological research in the national scheme. A great deal of effort has gone into guided missiles, weapons, and into fundamental research in high energy physics and reactor physics. In the process, until very recently, the fundamental biological studies have not had the research support which they should have had. Some of this is apparent in the fact that a biology doctor of philosophy can expect to earn rather less than a physics doctor of philosophy, even though his field of work is definitely of more human value and should therefore be paid more highly. It is hoped that the committee will look into the use of Atomic Energy Commission funds for the support of research,

and to see whether there is a disparity between the physical and the biological sciences.

GENERAL STATEMENT OF RADIATION AND CELLULAR PROCESSES

With the limited understanding that we have, we can say that no living cell which has received the effects of penetrating radiation is the same as before. By this I mean that if a group of ionizations are released within a cell they will cause an alteration at the point where they were produced which will either damage a molecule of importance to the cell, or produce effects which will have the equivalent of poisoning a molecule not far away.

Once this alteration has been produced it may well be that the cell appears to recover, but if it does so it is solely because it has not been put in circumstances requiring its full capability. There is no evidence from our work that any appreciable part of radiation damage is restored fully.

Therefore, radiation puts a heavy demand on the replacement of cells. This replacement may not be perfectly achieved; by which I mean that a new cell which is grown from a healthy cell may not be exactly the same as the one which was damaged, and which had to be replaced. In this case, as time goes on and these cells divide, more and more there may occur long-delayed effects. These are due to the fact that the replacement cell did not contain exactly the right complement of parts for some function later in life. In this case late effects are to be expected, and they are found.

RADIATION WITHIN AND WITHOUT THE ORGANISM

Radiation produced from within the organism could only be less effective for one reason—burial in nonactive material. The burial would have to be deep and the material would have to be quite definitely nonactive. This to my mind is highly doubtful because there seems to be little or no nonactive material in a living human being and also the depth to which the burial would have to occur exceeds that of the thickness of most bone. So I would feel that it would be highly doubtful that radiation from within the organism could ever be less effective than that from without. Otherwise one would expect it to be equal. It could, however, be more effective. This would be the case if the radioactive element were part of a chromosome or any essential cellular element. This increased effectiveness has been observed for P–32 in viruses and bacteria. No work has yet been done on Sr–90 or Cs–137 in simple organisms. It should be done.

To summarize, I would be surprised if the effectiveness of internally applied radiation exceeded external by twofold, very surprised if it exceeded by tenfold, and I would find it even more surprising if it proved to be less effective than external.

BEARING ON PRESENT TOLERANCES

The presences of a microcurie of Sr–90 could in 1 year cause serious damage to at least 10^{12} cells. This is an appreciable fraction of the cells invaded or approached by Sr–90. It would seem unwise to consider such a stress on cell replacement as "tolerance." K–40, which is tenfold less in amount and spread far more widely, does less damage and yet it may be a significant factor in ultimate aging.

It would seem very unlikely to me that it would indeed be true that the effects of 1 microcurie of Sr–90 in even a small fraction of the population would not be clearly observed after 30 years of observation.

It seems to me that there is too great a tendency to apply laboratory tolerances to the whole world population. Pollution in the air of a chemical laboratory which is borne cheerfully by chemists would be intolerable in the atmosphere of a city. Therefore I suggest a reduced maximum tolerance and the policy of regarding all radiation with suspicion.

Representative HOLIFIELD. Now we will invite the following persons foward to the conference table to discuss today's testimony: Dr. Friedell, Dr. Brues, Dr. Lewis, Dr. Hardin Jones, Dr. Ernest Pollard, and Dr. Shields Warren.

There has been some conflicting testimony today and I am not just sure how to start, but certainly Dr. Lewis' testimony and that of Dr.

Furth are in contradiction to each other. As long as Dr. Warren had the last say on Dr. Lewis' testimony, I would like to ask Dr. Lewis—would you like to make a comment on the criticism of your statement?

DISCUSSION BY DRS. H. L. FRIEDELL, AUSTIN BRUES, EDWARD LEWIS, HARDIN JONES, ERNEST POLLARD, AND SHIELDS WARREN

Dr. Lewis. Thank you, Mr. Chairman. I made the point near the end of my testimony that the conclusions that I arrived at did not depend in any way upon assuming that leukemia results from a somatic mutation. I believe that one of the objections was that I had assumed that leukemia was due to such mutation.

Another possible criticism, I believe, was the implication that radiologists have received tremendous doses of radiation as evidenced by claims in some quarters that they have experienced a 5-year reduction in life span. I would estimate that the average radiologist did not receive more than about 10 roentgens per year of occupational exposure, judging from the place on the chart where the slant line intersected the green, dashed line. This suggests that radiologists as a group should not experience the marked decrease in life span that some have claimed.

In my opinion, radiologists do not suffer more than a 1-year reduction in life span. This conclusion is supported by the studies of Dublin and Spiegelman for the period 1938 to 1942, which indicate that radiologists live longer than physicians.

Representative Holifield. You used 1938 to 1942?

Dr. Lewis. That is correct, but I have also extended the observation to 1952. I should hasten to add that radiologists do not live as long as medical specialists. Medical specialists are a select group. They have a life expectancy greater than the general practitioner. Radiologists belong to the group of medical specialists, but they do not live so long as the average medical specialist. So, radiologists do suffer some reduction in life span, but probably much less than a 5-year reduction. This means that radiologists have probably averaged much less than 1,000 r. as a lifetime absorbed dose.

I do not remember other points now that I would care to comment on. I hesitate to do so, in any case, since Dr. Furth is not present today.

Representative Holifield. Dr. Jones, would you care to comment on what Dr. Lewis has said, and then we will ask Dr. Friedell.

Dr. Jones. Yes; I would. The radiologists in my opinion do show a life span shortening effect. The analysis is somewhat complicated. It began with Dr. Shields Warren's study of the average age at death of radiologists, which showed it was approximately 5 to 6 years less than for physicians in general and indicated radiologists would live less long. There is also Dr. Lewis' own study, in which he arrived at a different conclusion; however, by looking at the current distribution of ages in the radiologists, one could show there is a very marked shift in the age distribution toward the younger men, because they have come into the field relatively recently. The whole population of radiologists is expanding. Over the last 20 years, it has expanded by a factor of two, at least. It means that the use of approximate

methods of analysis, such as "age at death," can lead to erroneous conclusions.

Using Dr. Warren's data, where I have a list of the ages of the radiologists who died, and also Dr. Lewis' population census of radiologists, and putting these together, we can analyze the data in one of the usual ways of looking at vital data, by finding age-specific death rates of radiologists.

We find, for radiologists up to age 50, the death rates are quite comparable to the average white male deaths in the general population, and are quite comparable to the death rates seen in physicians as a whole. Above age 50, one finds there is an increasing death rate in radiologists, which is quite pronounced at ages 65, 70, and above, where ultimately the radiologists are dying twice as fast as the general population and all physicians of the same age.

Senator JACKSON. From a scientific standpoint, would you say that the data are fairly accurate on a comparative basis? Are these people dying of heart attack and so on? Would you say that was induced by their profession or work? I am just asking the general question whether you feel that the data from a scientific standpoint are reliable.

Dr. JONES. The way life-shortening effects of harmful conditions in general work, including the effects of radiation, is that average ordinary causes of death come on sooner than they would otherwise.

Senator JACKSON. Does it follow that the work in radiology is the proximate cause?

Dr. JONES. One is looking for small absolute values, and one must be very, very careful. We do not know, in this case. It would be the thing that we would suspect as the foremost of the list of things that we could suspect.

Senator JACKSON. Are there other specialists outside the medical field who die in the same age range?

Dr. JONES. I think it would be very worthwhile to examine mortality data for all the medical specialists and do it in the same way. I would also recommend that a much more thorough study of radiologists be made.

Senator JACKSON. Unless you get accurate case histories and run down a series of them and find out exactly what they died of, how could you really determine that their work in their profession is the proximate cause of shortening of their life?

Dr. JONES. You may not be able to determine this, even after you have run down case histories. These are very difficult things to do.

Senator JACKSON. Is not this necessary if you are going to have good data from which to make your conclusions?

Dr. JONES. I am sure we would all agree we would like to have much more accurate data on all things of this sort, but significant conclusions may be possible even from the limited data available.

Dr. WARREN. If I might make a comment here, Mr. Chairman, I think that one of the striking things about the effect of radiation in shortening life is that there is no specific means by which it shortens life. You cannot pick out a particular disease and say, "This is the cause of radiation life shortening. You have to take the overall picture. Whether you deal with mice or fruit flies or rats or dogs, pigs, goats, humans, this general trend of life shortening shows up all the way through, not from any one specific cause. I think this is somewhat comparable with the mutation effect. The rate of muta-

tion is increased, but there is no mutation that is characteristic of radiation. There are a great variety of mutations that are brought about. I think this goes back to the very sound point made by Dr. Pollard and some of the earlier speakers, that the significant changes are changes that take place in the fundamental building blocks of our cells, and the manifestation of these changes may be apparent in quite a wide number of ways.

Representative HOLIFIELD. Dr. Jones, do you have something to add?

Dr. JONES. When I have my next turn, I will have something to say.

Representative HOLIFIELD. Dr. Friedell, do you have a comment?

Dr. FRIEDELL. I have no prepared comments. I think I would have to state my position as saying that I am concerned by what these gentlemen have said, but not yet fully convinced.

First of all, I think you want to make sure that the selection of cases from both groups are exactly the same. Apparently evidence is being presented which shows these may be comparable. I think it is important to show that the activity of radiology itself does not attract into it people who are likely to have a higher death rate, especially at the higher ages, because very early in radiology an individual who had one sort of illness or another was often given the advice to enter radiology, because it appeared to be a sedentary occupation. I do not know whether this in any way alters the figures at all, but I think it is well to look at this from every point of view. It is difficult trying to make this decision from the statistics alone.

An example of how this might occur is something that was presented by George Bernard Shaw many years ago. He was violently opposed to immunization as I think many of you know. Statistics were presented to him to show that as immunization increased, various communicable diseases decreased in England. He hired somebody to count up the telegraph poles erected in various years in some particular streets, and it turned out that telegraph poles were being increased in number. He said, "Therefore, this is clear evidence that the way to eliminate communicable diseases is to build a lot of telegraph poles."

All I would like to say here is that the important point is that if you really want to understand it, you have to look at the mechanism of the occurrence. I think this is where the emphasis should lie.

I am very pleased to have Dr. Pollard speak to this matter as he did this afternoon.

Representative HOLIFIELD. I will withhold my remarks until I ask Dr. Brues to comment, and then back to Dr. Jones.

Dr. BRUES. I think a lot of specific comments have been made. I would like to make a sort of general one about scientific evidence, because that seems to come up here.

If you have two experiments with the same kind of mice treated in the same way, you will expect the second one to come out the same way the first one did. You take a prediction of that sort as simply representing honesty on the part of the investigator. That is why the experiment was repeated in which the irradiated mice lived a little longer because it was difficult to believe, and needed to be confirmed. I think perhaps a lot of our experiments that came out the "right" way should be repeated also.

The next experimental evidence is where you irradiate one kind of mice, and then you infer from that that some other sort of mouse will behave in the same way. That is not quite so scientific a route, and you have to spread your work out a bit to get the answer.

Then there is the third situation where you do an experiment, having to do with a certain situation, and you transfer the results of that quite a distance. You demonstrate a certain percentage of life shortening at a high level, and you guess from this that you will see a certain amount at the low level which it would be impossible to ever detect. Or you study it in the mouse and you multiply the result by the difference in the life spans, and you come out again with a figure. When this is mixed up with mechanisms that you have no way of looking at, it becomes a little more speculative.

I find personally that Dr. Lewis' figures are extremely interesting and suggestive. I think that probably some of the warmth of the statements that have come out in relation to this are owing to what some people have perhaps done to Dr. Lewis' work, saying that so many leukemias will be produced under certain conditions. I think if we look at it that way, we are perhaps a little less in danger of overweighting our thoughts on the side of radiation hazards and forgetting a lot of other things that are important and related.

Representative HOLIFIELD. Thank you. Now Dr. Jones.

Dr. JONES. I would like to go back to the leukemia study, particularly among the Japanese. It is unfortunate but there is a great deal that is unknown about these people. We do not know the doses that go with any individual person with any certainty. When I say "any certainty," the uncertainty in this case is a very large number. Many of these cases appear to have received, on the record, doses that may have run 5 to 10,000 r., and yet some of these individuals have essentially shown no radiation symptoms, in spite of being out in the open. These are rather unbelievable upper limits of radiation doses to have produced no visible effects.

On the other hand, there are other individuals on the record who reported severe radiation symptoms under circumstances where, because of the geometry, they have received only 5 r., or less.

It is possible to do some major reconstruction of the data. I myself believe that the thesis that Dr. Lewis presents is a very good one to go by at this time, namely, that the induction of leukemia by radiation is proportional to the dose. Everything we can test critically here suggests the idea of proportionality.

In the first place, the individuals who first put this tentative data together—the most tentative, I guess, ever put together for humans under critical assessment—thought that the evidence suggested that no leukemogenic effect occurred until some threshold dose was reached. Since they are the primary individuals who put this data together, I think their conclusions should be kept in mind as we go on with other considerations. I prefer not to go along with this hypothesis of a threshold effect, but I think the scientists ought to weigh their evidence carefully.

If we do the best job we can—I have spent much of my time trying to reconstruct this data myself—and look at the individuals whose symptoms show that they got definite exposure, and we can estimate the dosage rates to go with these symptoms, then the story that Dr.

Lewis presented to you becomes quite intensified. Instead of finding the probability of leukemia to be one chance in a million per person per roentgen exposure per year of life lived after exposure, the probability would be 5 times this value, or 5 times 10 to the minus sixth chances of leukemia per roentgen exposure per person alive a year after exposure. This means that the chance of developing leukemia may be very much greater than Dr. Lewis estimated. If it is this larger value which is applicable (and it is not the upper limit one could derive from this data, but simply one plausible estimate), it would mean that the 3 to 5 roentgens of natural radiation that the Japanese ordinarily received, just as Americans ordinarily receive this amount in their lives, would account for the reported incidence of leukemia among the general population in Japan. This is something we cannot conclude today, but it is something we ought to keep in mind, because this is what the data may really mean when we finish analyzing them.

I think that this kind of information warrants development to the utmost refinement, because we are going to have to make a great many practical conclusions based on this kind of evidence.

Representative HOLIFIELD. Dr. Friedell.

Dr. FRIEDELL. I intended to make some comment about the curves that were drawn here with regard to the incidence of leukemia and dose. I feel that if we leave out other considerations that help the data, and look at the data as they exist, we find that it is not possible to make any conclusions about the low doses. This has been amply discussed by everybody who has examined this, including Dr. Lewis, who presented it this way.

I would like to point out that really one of the important decisions is not what the incidence of radiation is at high levels so much, and not whether radiation at higher levels will produce effects, but whether there really is a threshold or not. Thus when we get into the very low dose levels, we are going to talk about whether leukemia can occur. I feel that the data presented here do not permit us to make this kind of conclusion.

I would like to point out that the way that these data should be presented is to draw some kind of distribution curve about each of these points. You can estimate quickly what the chances are that the lowest point would be at that level. It could be easily 6 plus 2½ or 6 minus 2½ two-thirds of the time. The same thing is true of the other point listed as six. This is one standard deviation. Therefore, the way to draw the number would be a spread in which you could draw several kinds of curves. I might add that this is perhaps a good first approximation, and it is reasonable to examine it this way, but I would also submit that it is not possible from these data alone to conclude at very low levels or small doses that you would necessarily have some biological effects, such as leukemia, specifically, in this case.

This kind of argument could be used for one molecule of cyanide. You could argue that 1 molecule of cyanide introduced into the body would find 1 cell on which the organism really depends, and therefore there is no threshold for cyanide. The truth of the matter is that toxicologists cannot come out with this kind of explanation unless they use the reasoning I proposed.

The other thing that could be said about this is that a reasonable way of writing this data is to put it on logarithmic type curves which

markedly extend the lower end of this to give you a good idea of how long this dotted line really is. This perhaps would be a fairer way of looking at the data so that people who may be uninitiated in this would not necessarily conclude that very low doses will surely result in leukemia.

On the other hand, I think there is evidence to indicate that we better look seriously at the idea that a single hit is effective. Therefore, I don't feel that we can in any way exclude this, but I think we ought to have some kind of reservations about how quickly and how rabidly we use these data to apply them to any decisions we have to make.

Representative HOLIFIELD. Dr. Pollard, would you have something to say on that?

Dr. POLLARD. I really do not have a great deal. It does seem that the linear line is very reasonable, I would personally be surprised if it were not something like this. Really, the only thing I can say is that I feel tolerably confident that the primary radiation damage is severe, and probably acts on the genetic part of the cells, somatic or not. What results from this, whether that cell becomes more sensitive to a virus or what occurs, I don't know. I would be very surprised if it took a lot of nagging away at that cell to produce an effect. It would either be "bingo," and it has got it, or not, and that would give the linear kind of relation.

I think the linear line is rational. I would like to see policy momentarily at least based on it. If later on it seems there is a threshold, then we are not too badly off. But if there is not a threshold, and we bet there is one, we are in trouble.

Representative HOLIFIELD. Dr. Lewis, we will let you have a rejoinder, and then we will have a 2- or 3-minute summation on this problem of threshold, and we will conclude the hearing.

Dr. LEWIS. Thank you, Mr. Chairman. I would like to go back to the point about the six individuals in the dotted portion of the curve. Remember, I said that in the zone from 1,500 to 2,000 meters there were 10 individuals who died of leukemia among 23,000 survivors; whereas, in the zone beyond 2,000 meters there were 26 cases among 156,400 survivors. The point has been challenged that this is not statistically significant—the difference between these two zones. I have not been able to put on the chart all of the figures. The figures are published in a paper, which by the way does discuss the statistical significance of the results.

Representative HOLIFIELD. Are you referring to the article in the Science Magazine of May 15?

Dr. LEWIS. Yes. I want to go back and point out that no survivor in the zone from 1,500 to 2,000 meters could have received more than approximately 100 rem. That is, 100 rem is the maximum dose in either city at 1,500 meters.

Beyond 2,000 meters there was esentially no dose at all, so there was a "control" zone. "Control" meaning here was a zone in which the people got essentially no radiation. It was much less probably than 10 r. There were 26 cases among 156,000 in this control zone, compared to 10 cases among 23,000 in the 1,500- to 2,000-meter zone. If you apply the statistical test for comparing the difference between two such frequencies, it is significant at a level that is called 2 percent. That means there are 2 chances in 100 that this could happen.

That is something that we ordinarily operate on to mean that it is not due to chance. In other words, the two zones we are considering differ significantly with respect to incidence of leukemia.

We would like to see the chance one in a million.

Representative HOLIFIELD. How reliable do you consider the Hiroshima dose curves?

Dr. LEWIS. As an upper limit they are very reliable since the physics of the atom bomb burst is what sets these so-called air doses which are upper limits. Where the uncertainty comes in is how much the survivors absorbed and whether the people were evenly distributed or not. There is still, I think, a need for a breakdown on the census figures. I think that the census material is available. I have assumed that the survivors were pretty randomly distributed throughout the zone.

Representative HOLIFIELD. Dr. Warren.

Dr. WARREN. I would not like to make any added comments on the threshold matter, but I would like to speak to the reliability of the data at Hiroshima and Nagasaki. These are as reliable human data as we have. Fortunately, there are careful studies now being made of reconstructing as nearly as possible the conditions under which the various survivors found themselves. This is a little hard to do a number of years afterward. But fortunately, in some we had fair detail quite early. I would feel that the dose levels of these individuals eventually can be calculated within plus or minus 25 percent. This is a very difficult and tedious job, because the geometry varies for each of the people involved. For example, in one building in which we studied in Hiroshima, which was within the 1,000-meter zone, there were 88 who died, 3 who survived. In subsequent study of the building, it was found that the three who survived were heavily protected by earth and cement, and approximate reconstruction can be very soundly worked out for them.

I think there is this important thing to remember, that in this whole field of radiation biology we are working on a relatively new type of research in which very few people were interested originally. When I was first interested in 1925, there were not more than 10 or 12 other people in the world interested in it. This interest and importance has been built up very rapidly. However, there were so many things to be learned that the picture had to be roughed in in very broad sketches at first, and then more and more of the detail filled in.

Our initial studies at Hiroshima and Nagasaki in September 1945 and from then on were very crude studies, indeed. They had to be. We were working vitrually without facilities, with thousands of injured patients for whom we had to care with the aid of our Japanese colleagues, who did a very fine and wonderful job. We had to learn what we could. At the same time we were trying to impart to our Japanese colleagues the knowledge that had been gained of antibiotics and other things.

That is simply to illustrate that many of these fine points will have to be worked out. There is work here for 25, 30, and 50 years before all these points can be answered. I think that we are now at the stage when many of the essential landmarks, at least, have been recognized, and we can go to a much more detailed and accurate survey.

Representative HOLIFIELD. Thank you. Dr. Warren, one of the staff members has told me that you have to be excused to catch a plane

very soon. Do you care to make any further comment, and then the Chair will excuse you if you wish to leave.

Dr. WARREN. Thank you very much, indeed, sir. I have about 15 minutes more I can spare before I go, and, because I am deeply interested in this, I would like to stay.

Representative HOLIFIELD. That is fine. Would you start the summary, then, on the question of the threshold?

Dr. WARREN. Yes. I have favored the concept of a threshold for most carcinogenic agents for a number of reasons. First, that in our experiments with carcinogenic hydrocarbons, which are known to be derived from such substances as coal tar, we find that a threshold exists for them. We find that, with many of the medicines that are commonly used for one or another effect on cells, there is a threshold effect to these medicines. We know, by analogy with simple things in physics, there is a threshold effect. For example, I can push very lightly against this stand of the microphone, and it will not move until I reach the threshold of where that push is greater than the friction which tends to hold it still.

I like to think of this reparative force, these agents and others which Dr. Furth mentioned, as being things which counteract the effect of very low level radiation. As I said, it is hard for me to believe that the cells that I know have been irradiated to a significant degree in this part of my wrist are any different from the adjacent cells. Of course, in that area, small as it is, there are tens and hundreds of thousands of cells involved.

I quite agree that it is entirely possible that I am wrong and that others are wrong. In fact, physicists were positive for many years that there could be no such thing as a solution of the atomic-energy problem, and that the atom was the ultimate extent to which matter could be subdivided. That has been proved wrong. I could be wrong. I think here, where we are dealing with matters of national policy, you need to be concerned not with possibilities—and I will admit that the threshold idea is a perfectly good possibility—but, rather, to weigh relative probabilities. I do not regard the complete linearity of the induction of leukemia as in the range of a reasonable probability. I would not rule it out as a possibility. Thank you very much.

Representative HOLIFIELD. Thank you. Dr. Brues, would you like to summarize?

Dr. BRUES. I might add just a brief word gained in justification of the possibility that there is a threshold for the production of cancer. I think, as we see experimental cancer and a lot of cancer occurring in human beings, we are impressed with the fact not that it is just something which strikes like lightning, although, indeed, many times it appears to, but that it frequently appears in a tissue which for some reason or other is already somewhat disarranged, and the lightning tends to strike in those places.

I think this concept might perhaps bring a little compatibility between the gene type of notion and the notion that some of us who have been in clinical work seem to adhere to, that there may not be a complete threshold, but there is something apparently close to being a threshold.

I would also say that although someone mentioned that if we don't take this no-threshold business very seriously, we may be in real trouble, I think we have to consider how much trouble we are in on

the basis of the natural environment in any case. We don't worry about the trouble we are in because someone invented fire.

Representative HOLIFIELD. Thank you. Dr. Jones.

Dr. JONES. This shows how much disagreement there is among us, because I think most of the evidence which exists shows that apparent thresholds are better explained in terms of the continuous probability of these effects occurring. We are dealing with the same body of facts in arriving at these varied conclusions.

Part of the difference is in the way people look at small quantities. In very small doses, you get very small effects. It is very easy to say that very small effects are zero, and then you have the threshold concept. If very small effects are just that—"very small"—then you do not have a threshold phenomenon. It is troubles of this sort that we get into when we have to multiply huge populations by very small numbers approximating zero.

Tomorrow, when I have a chance to talk at further length, I will show you much more evidence to establish the principle of proportionality in some of these effects.

Representative HOLIFIELD. Dr. Friedell.

Dr. FRIEDELL. I think I have expressed myself. I feel that the data at the very low levels are perhaps presumptive and even highly presumptive. I like the eternal consistency of the data on mutations better than any other purely from an examination of these data. I feel that the situation is not as yet established and not clear, and not conclusive. I don't really know how to suggest that this will be clarified except what I said earlier. I feel strongly that understanding the mechanism rather than looking at the statistics of the problem will give us a much better picture of the whole thing.

Representative HOLIFIELD. Dr. Pollard.

Dr. POLLARD. I would agree with Dr. Friedell's last remark. I would like to say that whereas from my point of view there is always damage to the cell, the question is really how many cells does the body have available to repair this and to what extent do these vary with lifetime, with the condition of a person, and so on. This is the broad realm of ignorance which I think we all agree we are in, and to escape which we have to do a great deal of work. I merely suggest again that the conservative thing to do in obtaining that knowledge is to assume linearity and therefore no threshold.

Representative HOLIFIELD. Dr. Lewis.

Dr. LEWIS. I would like to point out one thing more and that is that if we assume this straight line, this linearity as it is called, this absence of threshold, all these things being essentially the same thing, then we come up with these figures which I am afraid can be twisted to alarm the public unduly. I do think that the danger comes in legislating a dose that is said to be permissible for the public.

Representative HOLIFIELD. You used the word "legislation." You did not refer to the work of the committee, did you?

Dr. LEWIS. I beg your pardon. I meant standards set by Government agencies for the public. It would be better to state to the public that there is a distinct possibility that the so-called permissible dose will hurt a definite number of people. The number damaged will be relatively small we think for small doses, such as from fallout which is what we are talking about. But the percentage or the number who are expected to be damaged should be stated, instead of implying that

there is no danger from fallout or that the permissible dose will cause no damage.

Representative HOLIFIELD. The chairman will not try to summarize the summaries, but could the Chair ask this question? In referring to these incidents of leukemia or the mutation of genes you are all agreed, are you not, that you are referring to a low level of radiation which has occurred to date as a result of bomb testing, and that you are not referring in your statements today to a drastically increased rate of release of fissionable material into the atmosphere, nor are you referring to the incident of a nuclear warhead.

Dr. WARREN. Yes, that is our understanding, I believe, Mr. Chairman.

Representative HOLIFIELD. That is the general understanding of the panel. I see you nodding in assent and as the nods do not appear on the record, the Chair will state you are in assent.

The committee will resume its hearings tomorrow in the Old Supreme Court Chamber in the Capitol, room P–63, at 10 a. m. We will lead off in the morning with Dr. Crow of the University of Wisconsin. He will be followed by Dr. Glass, of Johns Hopkins; Dr. Sturtevant, of the California Institute of Technology; and Dr. Muller, of the University of Indiana. A general discussion will follow to wind up the morning session. In the afternoon we will have Dr. Russell, of Oak Ridge; Dr. Jones, of the University of California Radiation Laboratory; and Dr. William Looney, of the Massachusetts General Hospital.

Thank you, gentlemen, for being our witnesses and participating in the discussion.

(Thereupon at 5:05 p. m., Monday, June 3, 1957, a recess was taken until Tuesday, June 4, 1957, at 10 a. m.)

CONTENTS

(Part 1 also contains statements by leading scientists, together with statements and papers submitted for the record.)

(A detailed subject index is now being prepared and will be published at a later date.)

[1] Each witness was asked to submit a short professional biography. Most, but not all, of the witnesses did, or, as in the case of some Government witnesses, their departments did. In a few cases the biographies came from American Men of Science.

In some cases the JCAE staff has abbreviated or deleted from the biography, for brevity, no matter what the original source. These biographies are for information only and should not be regarded as a formal statement.

THE NATURE OF RADIOACTIVE FALLOUT AND ITS EFFECTS ON MAN

TUESDAY, JUNE 4, 1957

CONGRESS OF THE UNITED STATES,
SPECIAL SUBCOMMITTEE ON RADIATION OF THE
JOINT COMMITTEE ON ATOMIC ENERGY,
Washington, D. C.

The special subcommittee met, pursuant to recess, at 10 a. m., in room P–63 of the Capitol, Hon. Chet Holifield, chairman of the subcommittee, presiding.

Present: Representatives Holifield, Durham (chairman of the Joint Committee), Cole, Van Zandt; Senators Anderson, Hickenlooper, and Bricker.

Also present: Professional staff members: James T. Ramey, executive director; George E. Brown, Jr., Hal Hollister, staff technical adviser, and Paul C. Tompkins, consultant.

Representative HOLIFIELD. The committee will be in order.

This morning we continue our hearings on the effects of radiation on man, and we get into the area of genetics this morning.

Our first witness, Dr. Crow, is professor of genetics and zoology at the University of Wisconsin.

STATEMENT OF DR. JAMES F. CROW, PROFESSOR OF GENETICS AND ZOOLOGY, UNIVERSITY OF WISCONSIN [1]

Dr. CROW. Mr. Chairman and members of the committee, my intention is to summarize briefly and nontechnically the present knowledge of the genetic effects of radiations in man. I want in particular to indicate the sources of the data on which our conclusions are based, and give some idea of the reliability of quantitative estimates of genetic damage.

Previous statements before this committee have dealt mainly with effects on the person who receives the radiation. My discussion will be restricted to effects on his descendants; that is, to inherited effects.

I believe I can best summarize the general information on this question by stating four well established principles that are necessary background for any discussion of possible genetic hazards to man.

1. All high energy radiations increase the rate of mutation. A mutation is a change in the hereditary material of the cell, a change in the genes and chromosomes on which our heredity depends. An

[1] Date and place of birth: January 18, 1916, Phoenixville, Pa. Education: A. B., Friends University, 1937; Ph. D., University of Texas, 1941. Work history: Instructor and assistant professor of zoology, Dartmouth College, 1941–48; assistant professor, associate professor, and professor of genetics and zoology, University of Wisconsin, 1948; associate managing editor of Genetics, 1951–56; member of editorial board of Genetics; member of board of directors, American Society of Human Genetics; member of the council, Society for the Study of Evolution. (Submitted by witness.)

example of a multational change is that producing the bleeding disease hemophilia, characterized by abnormal blood clotting. Mutations can occur in any part of the body, but from the standpoint of heredity the important ones are those that occur in reproductive cells and are transmitted to the children. Thus, to have an effect on future generations, radiation must reach the reproductive cells sometime between conception and reproduction.

2. Almost all mutations that have been studied have been harmful.

Representative COLE. Will you repeat what you have said?

Dr. CROW. I said that almost all mutations that have been studied have been harmful.

Representative COLE. What do you mean by a "harmful" mutation?

Dr. CROW. One that in some way impairs the individual that carries this mutation. He might have his fertility reduced. He might be more prone to an early death. He might have most any kind of abnormality.

In general, most of the mutations that have been studied by geneticists have been in some way or another harmful to the individual.

Representative VAN ZANDT. After exposure to radiation?

Dr. CROW. That is right. I am talking about subsequent generations.

Representative COLE. What is a mutation?

Dr. CROW. Maybe the difficulty is that I have used mutation in two different senses. I have used the mutation as a change in the gene itself. What I should perhaps have said is that the consequence of that mutation in future generations has been harmful. I want to say, though, this is to be expected on purely theoretical grounds for the reason that a mutation is essentially a random change in an organism that is already functioning reasonably well. A random change is much more likely to be harmful than beneficial.

Consider, for example, a random rearrangement of parts in your television set. It is much more likely to make it worse than to improve its operation.

A point I want specifically to make here is that the typical mutation is not a gross abnormality.

Representative COLE. Let us be sure when you say mutation we are talking about the same change. You have indicated that you have used the word in two different concepts. To me a mutation is the consequence of some abnormality that has occurred in the ancestral genes. The result is the mutation. You have used mutation this morning as describing a damage to the parent genes themselves.

Dr. CROW. Yes.

Representative COLE. When you say mutation, let be be clear what we are talking about.

Dr. CROW. I am clear in my own mind, but whether I can make it clear in general is another question. Let me say this:

The mutation is the change that occurs in the gene, in the reproductive cell.

Representative COLE. Of the parent.

Dr. CROW. Of the parent. This changed gene is passed on to subsequent generations causing this varying amount of harm to the individuals that possess that changed gene in future generations.

Representative COLE. You mean that a changed gene inevitably passes that change on to the descendant?

Dr. Crow. That is correct.

Representative Cole. That an altered gene could not reproduce a normal child?

Dr. Crow. That is correct as far as the gene is concerned; the gene in the future that descend from the altered gene are altered.

Representative Cole. Is that always an accepted rule of genetics?

Dr. Crow. Yes.

Senator Bricker. How do you explain the fact, then, that there are always mutations going on in human regeneration, some caused, no doubt, by the normal background of radiation?

Dr. Crow. We have a certain amount of harmful mutation with us all along.

Senator Bricker. There must be some that are beneficial or there would not be the evolutionary process taking place in life.

Dr. Crow. That is correct. I did not say all were harmful. I said the great majority were harmful.

Representative Holifield. The great majority of the damaged genes are harmful, but the amount of damaged genes in relation to the total number of genes is infinitesimal, is it not?

Dr. Crow. It is small.

Let me answer Senator Bricker's point in a little detail.

Representative Cole. Before leaving this difference between infinitesimal and small; that is a tremendous area.

Dr. Crow. I agree.

Representative Cole. I would like to have you indicate on the record just what you mean by small as against infinitesimal.

Dr. Crow. Yes. Let me be a little more thorough about what you would like to know. You would like to know what proportion of the genes actually in the population are harmful versus that proportion which is beneficial?

I do not think the geneticists can answer that question in general. I do not think we have that kind of information. I can say that the proportion of sperms or eggs carrying a newly arisen mutant gene in any one generation may be of the order of 5 percent or so, perhaps as much as 15 percent.

That is what I mean by small.

Representative Cole. Newly arisen?

Dr. Crow. Yes. Newly mutated genes. By "newly" I mean having occurred in that generation.

Representative Cole. And out of that 5 percent, how many are harmful?

Dr. Crow. Practically all of them.

Representative Cole. So then your testimony is that 5 percent of the mutated genes are harmful?

Representative Holifield. Let us see if the Chair can understand.

The 5 percent that you spoke of was a rise in the rate of mutated genes. It did not refer to a 5 percent of the total number of genes. Am I right on that, or would you say that 5 percent of the genes are damaged, and the rate has risen to the point where 5 percent of the total number of genes are damaged?

Dr. Crow. I think I have confused this a great deal more than I have helped it.

Representative HOLIFIELD. No, we are the ones who have confused it, Doctor. You go ahead and straighten it out if you can. We will do our best to help you.

Senator BRICKER. Will you come to my question next?

Dr. CROW. Yes. Let me answer Senator Bricker's question.

The implication of your question is that if I say the great majority of mutants that occur are harmful, why is it that the great majority of genes that now exist in the population are beneficial?

The reason for this is natural selection. The mutant genes that have occurred in the past have been weeded out by the process of natural selection so that the genes which now are part of the normal population are those which have been retained by this process of natural selection. Therefore, even though the great majority of mutants at the time they occur are such as to cause harmful effects to the descendants, the ones which cause the most harmful effects are eliminated by natural selection. The genes left in the population are the beneficial ones.

Senator BRICKER. You would not say that all mutants are deleterious.

Dr. CROW. No. I did not say that. I said the great majority.

Senator BRICKER. There are some that are beneficial.

Dr. CROW. That is correct.

Senator BRICKER. Those are the ones naturally selected through the generations by the process of evolution.

Dr. CROW. Yes. May we go on from here? I am sure I have left the previous point in a state of considerable confusion. I think I can straighten it out as I go along.

Representative HOLIFIELD. Go ahead.

Dr. CROW. I think the things I say subsequent to this will straighten it out. So will the following speakers. I want to emphasize one point, though, and that is that the typical mutation is not a gross freak. Here I must rely largely on information from fruitflies, and this information tells us that the typical effect of a mutation is not a gross effect on the fly that can be seen but is much more likely to be something leading to the death of the fly and still more likely to be something that leads to an increased probability of early death of the fly without the certainty of it.

So the most frequent class of mutation that we can study in fruitflies is a kind that causes a slight impairment in the survival of these flies, but no obvious external effect.

I suggest by analogy that most mutations in man would produce various body impairments leading to increased susceptibility to disease, lower life expectancy, increased embryonic death rate and similar things.

All of these are occurring anyhow due to all sorts of causes and therefore it is ordinarily impossible to tell whether a particular instance of impairment or death is or is not of mutational origin.

3. My third main point is that one might perhaps think that mutations that cause only a minor impairment are unimportant, but this is not so far for the following reason: Deleterious mutant genes are eventually eliminated from the population since they generally increase the death rate or lower the fertility of the person carrying them. A mutant that causes a great deal of harm is eliminated in a few generations. But one that causes only a small amount of harm will persist much longer, and thus affect a correspondingly larger

number of persons. On the average the larger number affected by a mild mutation roughly compensates for the lesser effect on the individual.

Since minor mutations in the long run can do as much harm as more drastic ones and occur much more frequently, it follows that most of the mutational damage in a population is due to the accumulation of individual minor effects. This means that an estimate of mutational damage that considers only obvious hereditary diseases and conspicuous abnormalities is probably a gross underestimate of the total damage. The effect of minor mutations, though intangible in the sense of ordinarily being indistinguishable from the other ills that we are beset with, is probably in the aggregate much more important.

4. Evidence from experimental animals, principally Drosophila, indicates that the number of mutations produced is strictly proportional to the amount of radiation received. These are departures from this straight-line relationship at high doses, but these are too high to be likely to be encountered in any ordinary human situation. It is technically impossible to test this relationship for the very lowest doses, but the straight-line relation holds down to the smallest amounts that have been studied. Also from purely physical considerations, one would expect linearity at low doses. I have in mind the kind of analysis Dr. Pollard made yesterday.

For these reasons a simple proportionality between the amount of radiation and the number of mutations is fully accepted by geneticists.

The proportionality between dose and mutation production holds irrespective of the intensity or spacing of the dose. That is, 100 roentgens given at one dose is exactly equivalent to the same total given as a series of small doses over a long period of time. Also from the standpoint of future generations, it makes no difference whether one person receives 10 roentgens or 10 persons receive 1 roentgen; the effect on future generations is the same.

The total harm to the population, as measured by effects on future generations, is strictly proportional to the total amount of radiation received by the reproductive cells of the population.

Senator BRICKER. Regardless of the number of people involved?

Dr. CROW. Yes.

Representative HOLIFIELD. This, then, would establish as far as the majority of the geneticists are concerned the principle of linear progression in deleterious effects of radiation regardless of amount?

Dr. CROW. That is correct. A nonthreshold situation, to put this in yesterday's vocabulary.

This means that there is no such thing as a safe dose of radiation to the population. Any amount of radiation, however small, that reaches the gonads—testes or ovaries—of a person who may later reproduce, involves a risk proportional to that amount. The benefits of radiation must be considered in relation to this risk.

Senator BRICKER. I do not see how you distinguish that rational analysis with the radiation background that we already have.

Dr. CROW. I would say, Senator, that the mutations that we now have that are produced by earth background and cosmic rays are themselves harmful. It is something we have been putting up as a population for a great many generations. But I do not say it is good.

Senator BRICKER. This process of natural selection has overcome the deleterious effects?

Dr. Crow. That is correct.

Representative Holifield. Only to the extent that it has gradually by natural selection strengthened the race rather than allowing it to become weaker and weaker. To the extent that those harmful genes did produce weakened individuals, to that extent, speaking from an individual standpoint, there was no overcoming by natural selection.

Dr. Crow. Yes. Let me amplify that a bit.

The way natural selection usually operates is through death and disease and misery and the elimination of deleterious genes has been from our standpoint a cruel process. It is our concern with minimizing this that leads us to worry about the possibility of an increased mutation rate.

I would very happy if there were some way of decreasing the spontaneous mutation rate.

Representative Holifield. Let me go further, then, and ask if there is a tendency before fertilization or immediately prior to the fertilization of the ovum for a healthy gene to mate with a healthy gene, or is the tendency for a healthy gene to mate with one that is harmed by mutation?

Dr. Crow. I think I would say that the joining of sperm and egg is purely random and the sperm and egg is ignorant of its own content as far as the probability of fertilization is concerned.

Representative Holifield. Therefore, the fact that it is a random selection at that point results in either abnormalities or weakened individuals, is that correct?

Dr. Crow. That is correct.

Representative Holifield. You may proceed.

Dr. Crow. The statements thus far made rest on a great number of experiments on a large variety of experimental organisms—for example, viruses, bacteria, fungi, corn, insects, mice—and the results from one agree with those from others.

Furthermore, there is some direct, though fragmentary evidence for radiation effects in man from study of children of radiologists and of patients who had heavy therapeutic doses of radiation. Fortunately, biological effects of radiations have been extensively studied for many years and there is a large body of well established knowledge which we can make use of in the present situation.

Let me remark, parenthetically, that it is fortunate that the development of genetics preceded the discovery of nuclear energy. Two of the men who have contributed most of this development, Doctor Sturtevant and Doctor Muller, will follow me on this stand.

It was almost exactly 30 years ago that Muller first discovered that X-rays enhance the mutation rate in fruit flies. We now have a sufficient backlog of knowledge of radiation genetics to proceed into the atomic era with due caution for possible harmful genetic effects.

I want to say a little bit about the distribution in time of the effects of mutations that might be induced at the present time.

In the first generation after radiation there would be an increase in hereditary diseases. But, as emphasized earlier, most of the harm would be of a generalized sort, not overtly distinguishable from other human weaknesses. The total damage would be spread out very thinly over many generations, with the greatest amount the first generation and slowly diminishing amounts in succeeding generations.

Senator BRICKER. Does the same thing hold true with mental development as with the physical?

Dr. CROW. As far as we know.

Senator BRICKER. The same ratio?

Dr. CROW. I think so, sir, though nobody knows for sure.

Representative VAN ZANDT. Will this hold true regardless of the amount of the dose?

Dr. CROW. Yes.

Fruit fly data suggest that the mutations would probably persist for a long enough time, that half of the total damage would occur in 30 to 50 generations. I state this to give some sort of perspective in time as to what we are dealing with. In other words, I am dealing with something that is occurring over dozens of generations and therefore thousands of years.

Despite some uncertainty as to details, we can safely say this: The genetic damage from radiation is spread over a very long time in the future, with only a small fraction appearing in the first generation.

Representative HOLIFIELD. At this pont may I ask you this: If a person is damaged by radiation it will be entirely possible for that person to have normal children and those children not be damaged by the radiation, but the damage might appear in a grandson or great grandson?

Dr. CROW. Yes; or a great-great-great-grandson. Not only is that possible, I think that is the rule.

Representative HOLIFIELD. So then we cannot draw the conclusion that a person who has received a substantial dose of radiation, even though his children are normal, that there has not been damage done to the genetic pool.

Dr. CROW. That is correct.

Senator BRICKER. There has to be some radiation effect upon the genes entering into the first generation or it does not carry on.

Dr. CROW. That is correct, too. The genes themselves are damaged but they would not necessarily cause any damage in the person.

Senator BRICKER. The personality or the physical attributes of the first generation. If those genes are not affected in the first crossing then there is no deleterious effect?

Dr. CROW. In that particular generation?

Senator BRICKER. In that lot.

Dr. CROW. It is a little different point. We have gotten confused on the same point again. An individual that received from his parents a defective gene may or may not and usually will not shown any consequence of that particular gene. At the same time he has a certain probability of the effect showing up and some one of his descendants on the average will show the effect.

Senator BRICKER. But it is only a small minority of the genes in the parent that are affected.

Dr. CROW. That is correct.

Senator BRICKER. If the particular gene entering into the first generation is not affected deleteriously there is no effect upon subsequent generations.

Dr. CROW. That is correct.

Representative HOLIFIELD. But is it not true in the case of a female that at birth the female child has all of the supply of ovum that she will have for her whole lifetime?

Dr. Crow. That is correct, too.

Representative Holifield. So therefore somewhere in that chain of ova would be a possible harmed gene.

Dr. Crow. That is correct.

Representative Holifield. That is where it would come up in future generations. It would be that transmission of the total supply to each descendant which would carry forward the mutated genes as well as the normal genes.

Dr. Crow. Yes. What may appear as a contradiction between what Senator Bricker said and what the chairman has said is this point: Each time sperm and egg are produced there is a sampling process in which some of the genes are transmitted; some others are not. That means it is perfectly possible that a harmful gene a person carries will not be transmitted to the next generation. It is just as likely by chance that it will be transmitted twice as often to the next generation. I have ignored this fact since these chance effects cancel out in the long run.

Representative Van Zandt. Will you describe the nature of the effects on the succeeding generations?

Dr. Crow. I think the most important thing to say of the nature of such effects is that they are not of a specific sort. They are of the same sort of ills that you and I are already beset with. Decreased life expectancy and increased susceptibility to all sorts of diseases.

I want to make the point that genetic harm is not distinguishable in any way from other kinds of harm and that is what makes our problem so difficult.

Representative Van Zandt. Would it have a tendency to break down the resistance of the body to various types of diseases?

Dr. Crow. I think so.

Representative Holifield. For the benefit of the lay reader and the committee, could you not give us now on the board the chronological progression of the germ so that we could understand the different steps?

Senator Hickenlooper. Mr. Chairman, before he gets to that very complicated situation, I wonder if I could ask just one more question about this matter, which the chairman raised a moment ago, about damage to the ovum in the female.

Assuming that there is a radiation effect which might or might not damage the ova supply, would that tend to damage all of the ova or would it be selective after a fashion and only damage some?

Dr. Crow. I would say that the radiation acts completely blindly. Which particular future egg or sperm is affected as a consequence of radiation is entirely random.

Senator Hickenlooper. That is purely one of hazard or chance?

Dr. Crow. Yes.

Senator Hickenlooper. Do I understand you to suggest that under ordinary circumstances of exposure to radiation, not all of the ova or all of the sperm would suffer damage?

Dr. Crow. Yes.

Senator Hickenlooper. Let me ask you this as far as a female is concerned.

Dr. Crow. Let me make one statement first. This is where my first figure that I was mentioning a while ago comes in. I would suspect that in any particular generation from spontaneous normal causes

about 5 percent, perhaps more, of the sperms or eggs produced by an individual will carry a new mutation.

Senator HICKENLOOPER. Now we get down a little further to the practicalities of the situation. I presume your statistics and figures with regard to possible mutation or change or something of the kind that might enter in there would be based on an assumption that every ovum or every egg would be fertilized.

Dr. CROW. No.

Senator HICKENLOOPER. Out of that complete fertilization a certain percentage would be bad?

Dr. CROW. No.

Senator HICKENLOOPER. Which leads me down to the question of the whole supply of ova which a female may be born with and which she may produce during a life and how many of those in the normal course of human life are actually fertilized.

Dr. CROW. Only a small fraction, as you are pointing out.

Senator HICKENLOOPER. Does that alter or change your percentage?

Dr. CROW. No, I do not think it changes a thing, Senator. The particular ovum or sperm that succeeds in being fertilized or fertilizing is a random sample of all that are produced. The numbers are very large and I assume that we can use the kind of statistical analysis that one always uses with large numbers.

Senator HICKENLOOPER. Do I understand that you are suggesting that while a very small amount, percentagewise, of the ova that are produced are fertilized, that the percentage of injury to that small percentage that would be fertilized, would that be consistent as proportionate to the whole?

Dr. CROW. That is correct. The injury among those fertilized is exactly the same as those not fertilized.

Senator HICKENLOOPER. On the whole supply?

Dr. CROW. Yes.

Senator HICKENLOOPER. Thank you.

Dr. CROW. It should be emphasized that not all spontaneous mutations are due to radiations. Part are due to natural radiations—cosmic rays, ground radiations, radioactive isotopes in the body, et cetera—but many mutations, probably the majority, have other, mostly unknown, causes.

I am saying that most mutations are probably not caused by radiation at all, including natural radiation or manmade.

Spontaneous mutations that have occurred in the past probably, directly or indirectly, account for a substantial fraction of human physical and mental impairments. One way of attempting a quantitative assessment of possible radiation damage is to compare that due to manmade radiation with that from spontaneous mutation.

If I compare spontaneous mutation rates in man for those few genes that have been carefully studied with the radiation induced rate of mutation in mice, which is the best we can do because we have no quantitative data on man, one can estimate that it would require about 50 roentgens to produce by radiation a number of mutations equal to those that occur naturally.

I shall call this, as people have previously done, a doubling dose. That is, if your genes are as mutable as those of mice it would require about 50 roentgens to produce by radiation as many mutations as occur spontaneously.

Needless to say, this is subject to a considerable uncertainty. The National Academy of Sciences Committee on Genetics estimated 30 to 50 roentgens. The British Committee reached the same conclusion.

We, that is, the members of the Academy of Science Committee, have been told that the amount of radiation due to fallout at present rates would amount to something in the vicinity of one-tenth of a roentgen in a 30-year period. I shall choose a 30-year period because that is about the average age of reproduction. From a genetic standpoint this is the important aspect of the life cycle.

If a rate of one-tenth roentgen were to continue indefinitely, and the 50-roentgen doubling dose that I previously gave is assumed to be correct, this means that the population would eventually have an increase of one five-hundredth in genetic damage. Even if my estimate of 50 roentgens is much too high, the damage would still be a small fraction of the genetic damage due to other causes. The lowest possible value for this doubling dose would be of the order of 3 to 5 roentgens. That is, this would assume that only radiation can produce mutations and therefore all spontaneous mutations are due to background radiation.

Senator BRICKER. That is not always true.

Dr. CROW. No; I do not think it is true. I am trying to set a lower limit on the frequency of natural mutation or an upper limit on the consequences of fallout.

Representative COLE. Is it possible to distinguish the source of the cause of spontaneous mutations? They are not all caused by radiation.

Dr. CROW. No.

Representative COLE. Is it possible to segregate the causes of spontaneous mutations—those attributable to radiation and those due to unknown causes?

Dr. CROW. No; it is not. In any particular event one does not know whether this mutation is caused by radiation or something else.

As I said before, ordinarily one does not know whether a particular illness is caused as a consequence of mutation or not. In no case can we trace back a particular instance of disease to a radiation effect or to other kinds of mutational effect.

Representative COLE. By experimentation you can prove that radiation or induced radiation does result in mutations.

Dr. CROW. On a statistical basis; yes. Of course, in experimental animals the evidence is much more precise than this.

If I make this minimum assumption; that is, that all mutations that occur spontaneously are due to background radiation, and the fallout rate of one-tenth roentgen per 30 years, the mutational damage would eventually be increased by about 3 percent. That is, there would be a slow rise up to a point where the present damage due to mutation, whatever that be, would increase by a factor of about 3 percent.

Representative COLE. Doctor, how can you make that assumption, that all spontaneous mutations are the result of radiation?

Dr. CROW. I am trying to set a maximum on the effect of fallout. By setting a maximum on the effect of radiation I think we can set a maximum on the amount of fallout damage.

Representative COLE. In making that assumption you admit it is fallible.

Dr. CROW. Yes. It is a very unlikely assumption. I am trying to make an extreme assumption for the purpose of setting an upper limit. So I believe that we are completely safe in concluding that fallout at the present rates will increase the existing genetic damage by only a small fraction, even if continued indefinitely.

Representative VAN ZANDT. A body has 50 roentgens already.

Dr. CROW. Let me say the body already has a mutation rate equivalent to that produced by 50 r. of radiation.

Representative VAN ZANDT. Taking into consideration the present fallout, would it be increased by 3 percent over a period of 30 years?

Dr. CROW. My best guess was not 3 percent. My best guess was 1 part in 500. It might be as much as 3 percent.

Senator BRICKER. But there is nobody who believes that all the mutational changes in human life and the characteristics of body and mind are due to radiation.

Dr. CROW. I do not believe anybody believes that.

Senator HICKENLOOPER. Possibly do some of these mutations occur from chemical processes?

Dr. CROW. Very likely. I wish we knew the causes of all mutations but don't.

Although the general conclusions so far given are well established and there is no disagreement among geneticists, the quantitative assessment of human mutational damage is much less certain. There are no quantitatively reliable human data on radiation-induced mutation, and the figures from different experimental organisms are not in quantitative agreement. About the best we can do is to take the animal nearest man, in this case the mouse, as an indicator of possible human effects.

I think at this point there are two alternatives. One can say, as some geneticists prefer, that our quantitative data are so uncertain that we had better make no statements at all of a quantitative nature. Alternatively, we can say, as other geneticists do, that a poor numerical estimate is better than none at all. I belong to the latter group, so I shall, therefore, proceed to make some estimates as to the genetic consequences of the amounts of radiation involved in fallout.

Senator HICKENLOOPER. I am sorry to keep interrupting you, Doctor, but, may I ask, do some mutations have a beneficial effect occasionally?

Dr. CROW. I think a very small minority of mutations probably have a beneficial effect.

Senator HICKENLOOPER. We have had experience in mutations in grain where exposed to radiation, and I think the record shows that while in the overwhelming number of those mutations the progeny is less desirable than the ancestor, yet in a certain small percentage the mutations produced are in many ways far superior to the ancestry. Is that your understanding?

Dr. CROW. I think that is very likely true in man as well, Senator, but neither you nor I would suggest——

Senator HICKENLOOPER. I am sorry; I understand that you talked about that on the record before I came in, and I do not want to go over the same ground.

Dr. CROW. I have a sentence I want to say, anyhow. I think neither you nor I are willing to suggest that we sacrifice 999 persons with inferior mutations in order to get 1 beneficial one.

Senator HICKENLOOPER. I think we agree that is not even a 50–50, 1 horse and 1 rabbit, but I only wanted to be assured on the point that, in effect, not all mutations are bad and that if we have to have mutations there might be some modicum of benefit that would come out of it.

Dr. CROW. A very small amount.

Senator BRICKER. Would you say the percentage is 1 to 10 as to good?

Dr. CROW. No. It is much smaller than that.

Senator BRICKER. It has been proved between 5 and 10 in some of the grain experimentation.

Dr. CROW. I do not think so. I think the proportion of beneficial mutations that actually occur in grain or anything else is hardly higher than one in a thousand and may be much less than that. The reason the grainman can make use of this very rare beneficial mutation is that he can afford to throw out 999 of 1,000 grains and save the one that is superior.

Senator BRICKER. That is what they do. I thought the percentage was a little higher.

Dr. CROW. I do not think so, Senator. I think it is much lower. I do not care too much whether it is 1 percent or one-tenth of 1 percent or one one-hundredth percent. It is very small.

Senator ANDERSON. Was that the experience at Brookhaven when they were testing grain?

Dr. CROW. I do not know the exact figures.

Senator ANDERSON. Would that not be interesting to know?

Dr. CROW. I think it would be interesting, but I do not think it is too important from this particular consideration. It is very small, and that is what I am concerned about.

Representative HOLIFIELD. Is it not true that Burbank made thousands and thousands of experiments of crossbreeding in the plant field before he found a superior berry or superior fruit?

Dr. CROW. That is correct.

Representative HOLIFIELD. And that the actual cross-pollination and selection of pollen went into a thousand experiments before he found what he wanted?

Dr. CROW. That is correct. That is the way the modern plant breeder works. He grows thousands and thousands of plants, selects the one plant that shows the traits he wants, and throws all others out.

Representative HOLIFIELD. Which, again, proves the general statement that mutuations, generally speaking, are in the high proportion harmful.

Dr. CROW. That is correct.

Representative HOLIFIELD. Or degenerating rather than strengthening the strain.

Dr. CROW. That is correct.

I want to emphasize in these figures that I am about to present the large errors of measurement and the uncertainty of the assumptions involved in these estimates. To be concrete, I have prepared numerical estimates. I have prepared numerical estimates of the actual number of cases of different kinds of genetic harm that might be expected.

I shall assume a population of 2 billion children whose parents received an average of one-tenth roentgen. To repeat, one-tenth roent-

gen is roughly the amount that one might expect from fallout, according to the figures that have been published in a 30-year period. This may be too high; it may be too low. But it will give us a rough idea of the general magnitude of the risk.

Two billion is roughly the number of children that will be born in the entire world in the next generation whose parents have been exposed to fallout in this generation.

Representative VAN ZANDT. You are basing your figures on present-day test rates.

Dr. CROW. Yes. I am using the figures given to the Academy Committee and which agree with those published by Dr. Libby in his report last spring. Let me put some of these figures on the board, please. I think that is perhaps the best way to do it.

(The material on the board was as follows:)

Kind of damage	Number		Proportion of total population affected	Fraction by which existing abnormalities would be increased
	First generation only	Total for future generations		
Gross physical or mental defect	8,000	80,000	1/250,000	0.0001
Stillbirths and childhood deaths	20,000	300,000	1/100,000	
Embryonic and neonatal deaths	40,000	700,000	1/50,000	

NOTE.—Plus a larger but unknown number of minor or intangible defects.

Dr. CROW. I have written here rough guesses, which means that is what they are. I hope nobody takes the numerical values as being worth very much as numerical figures. They may be five times too high or low or more. I want only to give some rough indication, as I said before.

I am assuming that the parents had an average of one-tenth of a roentgen and there are a total of 2 billion children. I am going to give the number of various kinds of abnormalities both in the first generation and the total for all time, and I am going to give these figures in absolute figures, because these will be large, and then I am going to give them as percentage figures, and they will be small. That will make my principal point, as a matter of fact; the numbers are large, but the percentages are small.

Senator ANDERSON. Doctor, can I go back to the statement of yours a minute ago that quantitative data are so uncertain that we better make no statements at all.

Is it not possible that by taking these assumptions of yours that parents are only going to receive one-tenth and there will be 2 billion children born and so forth, that you are going to come out with some figures that are very reassuring that there is no danger in these tests, but you have no figures to back it up.

You keep making a statement that they are all right and then you say it is based on figures that do not mean anything.

Dr. CROW. I have not been sending out statements that it is all right.

Senator ANDERSON. You are about to make one as to the number of children based on assumptions. If I assume that today is Sunday I can prove it is only a 5-day week.

Dr. CROW. Let me finish my statement, Senator, and then come back.

Senator ANDERSON. It is the assumption that you start with. If there are 3 people up here and if 2 go the place is practically deserted, but there are more than that.

Dr. CROW. I say I have made what seem to me to be reasonable assumptions. That may be wrong. There is a high probability that numerically they are wrong. I still hold to the idea that we are better off estimating very crudely what the numbers involved here are than not making any numerical estimates at all. That is all I want to proceed with. I do not want anybody to take these more seriously than they deserve.

Representative VAN ZANDT. Dr. Crow, as I understand it, you are here to give us the benefit of your thinking.

Dr. CROW. Yes. I do not want to speak for geneticists as a whole or commit myself to any certainty as to actual numerical values.

The first category I want to talk about is gross genetic disease. I include in this both physical and mental disease, known or suspected to be of fairly simple genetic origin.

I would estimate something like 8,000 such cases is the first generation, and a total of some 80,000 all told. This would make up a fraction of about 1 in 250,000 in the population.

I have in mind here the kind of diseases that I referred to earlier. These may be serious mental diseases, serious physical diseases, deformities, mostly things of a rather clear hereditary origin.

In the second line we have death rates in childhood, including stillbirths. I will call this stillbirths and childhood deaths. The number I would give to this is 20,000, or a total of 300,000 for all time, making up in any one generation a fraction of about 1 in 100,000.

Then the final category I want to mention are embryonic deaths and deaths around the time of birth. I am going to call this neonatal deaths. I would guess for that 40,000 the first generation, 700,000 total, or a fraction of something like 1 in 50,000.

I have one other figure I would like to note and that is that these collectively make up about 0.0001; that is, approximately 1/10,000 of the normal incidence of these conditions.

I want to add at the bottom "Plus a larger but unknown number of minor or intangible defects."

I do not want to tell you in detail how these estimates were gotten. I would be glad if you like, to insert in the record the procedures by which there were obtained so that they could be independently checked by others.

Representative HOLIFIELD. I think you should do this.

Dr. CROW. I shall be glad to do that.

(The information referred to follows:)

PROCEDURES BY WHICH ESTIMATES OF GENETIC DAMAGE WERE MADE

These estimates ignore the effects of completely recessive factors. Such factors would have a probability of expression of much less than 1 percent in any 1 generation unless the amount of consanguineous marriage were high, or there were a high frequency of the mutant allele already in the population. The latter is not likely to be the case except for a few genes (such as thalassemia in some populations) that are maintained by some sort of selective balance. There is substantial evidence in drosophila, and some in mice and humans, that recessive genes generally have some effect as heterozygotes and that this effect is

large enough to constitute the main effect of these loci on the population. The early evidence has been summarized by Muller (American Journal on Human Genetics 2; 111–176, 1950) and there are recent confirmations. It therefore appears likely that most "recessive" mutants are eliminated as heterozygotes before they ever have an opportunity to become homozygous. My estimates are based on this assumption. I think this is reasonable as a first approximation. To the extent that the assumption is wrong the damage would be spread over hundreds rather than dozens of generations with correspondingly less effect on each, though the total effect would be about the same.

The mehods used in arriving at these estimates are explained in an article soon to appear (Eugenics Quarterly, July 1957). Briefly, they are as follows:

The number of gross physical and mental defects was obtained this way. The number of abnormalities of fairly simple genetic origin is estimated as about 2 percent of all children born (see "Genetics and Disease" by Tage Kemp, p. 190; National Academy of Sciences report, p. 25). Assuming a 50 r. doubling dose (National Academy of Sciences report, pp. 23–4; Muller, Bulletin Atomic Scientists, 11:336, 1955; Crow, Eugenics Quarterly, 3:201–208, 1957), 0.1 r. continued over many generations would lead at equilibrium to an increase of 0.1/50, or 0.002, in these types of abnormalities. The total effect over all time of 1 generation exposure is equal to the effect of 1 generation at equilibrium after repeated exposure. Thus, assuming a stable population of 2 billion births each generation, the total affected from one dose of 0.1 r. would be $0.02\times0.002\times2\times10^{9}$ or 80,000. The National Academy Committee suggests that about 10 percent of the damage would appear the first generation, making 8,000 out of 2 billion, or 1/250,000 of the population. The normal incidence of such conditions, genetic and nongenetic, is about 5 percent, so the 0.1 r. would cause an increase of 8,000/100 million=0.00008, or approximately 0.0001.

The estimates on stillbirths and childhood deaths are based on an estimate from the increased death rate in children of consanguineous marriages (Morton, Crow, and Muller. Proc. National Academy Sciences 42:855–863. 1956). This estimates about 8 percent as the proportion of stillbirths and childhood deaths at mutational equilibrium. Again assuming a 50 r. doubling rose, 0.1 r. would lead to an increase of 1/500, or 0.002. In a population of 2 billion this leads to a total number of $0.08\times0.002\times2\times10^{9}$=320,000 or approximately 300,000. Drosophila data suggest that the typical "recessive" mutant has about 4 percent dominance, and making a small allowance for inclusion of dominant factors, I estimate 6 percent of the damage the first generation. Six percent of 320,000 is 19,200 or approximately 20,000. The total death rate in these ages in the populations on which these studies were made was about 12 percent, hence the effect of 0.1 r. is 20,000/240 million=0.000083 or approximately 0.0001.

The data on embryonic and neonatal deaths come from Russell's data on radiated mice. When the father had 300 r., the litter size (counted at age 3 weeks) was reduced by about 3 percent (Proc. Intern. Conf. on Peaceful Uses of Atomic Energy. 2:382–383). If both parents received 0.1 r., the effect would be 0.2/300 as great. Hence the estimated first generation effect is $0.03\times0.2/300\times2\times10^{9}$=39,600 or approximately 40,000. Again assuming 6 percent the first generation, the total effect is 40,000/0.06=670,000 or approximately 700,000.

Dr. Crow. Let me give a rough indication.

These are based on statistical data on the frequency of such diseases and the assumption that mouse provides us a good indication as the radiation induced mutation rate. I have to use Drosophila data. The animal I am talking about here is in a sense a composite of a man, mouse, and fruitfly. To whatever the extent the information from these other organisms is relevant, these figures are reliable.

The stillbirths and childhood deaths are based on human figures for death in these ages gotten in a very indirect way that I do not want to take time to describe from the frequencies of different kinds of deaths in children of parents who were related. Once again I have to make use of fruitfly data in order to complete this estimate.

The third row of figures is based on embryonic death rates in mice in Russell's data. These are deaths that occur in mouse embryos and postnatally up to the age of 3 weeks.

Note that the second and third rows are not exclusive. Stillbirths and infant deaths are included in both groups.

I hope I have indicated that these all depend on mouse and fruitfly data and if man is different, the figures are no good. I think these are about as good an indication as one can get at this time.

Representative HOLIFIELD. There is no doubt that the mammal case would be much closer to the man than the fruitfly.

Dr. CROW. I think so.

Representative HOLIFIELD. The only reason for using, or the chief reason for using, the fruitfly is the rapid span of life.

Dr. CROW. That is correct. And the tremendous backlog of information in the fruitfly that we possess as a consequence of a great many years of work by geneticists.

Let me say in general that I have used human data when I could. When I could not, I used mouse. When neither human or mouse data is applicable, I have used fruitfly data.

I have one summarizing paragraph.

Despite the quantitative uncertainty of these estimates, I believe they have enough validity to permit some definite conclusions. One is that with the present levels of fallout, the amount of genetic damage in future generations from this cause will be a very small fraction of the total human death, disease, and misery. On the other hand, the number of persons exposed to fallout is as large as the world population, and therefore we can be sure that several hundreds, or thousands, or tens of thousands, or perhaps more persons will be diseased, or deformed, or will die prematurely, or be otherwise impaired as a consequence of fallout if the present rates of testing continue. In my opinion, even one unnecessary individual tragedy is too many, and no increase in radiation for any reason should occur unless it offers some compensating benefit for mankind.

Representative HOLIFIELD. Thank you, Dr. Crow. I am sure there will be some questions.

Senator HICKENLOOPER. Doctor Crow, perhaps you mentioned this, and I am sorry I was a little late in getting in, but did you discuss or have you studied or examined any data over a substantial period of time with regard to the Indians who live in the monazite sand district of India and the genetic data with respect to those generations that have developed in that monazite sand area?

Dr. CROW. My understanding is that a study of this is contemplated. I am not aware of any data yet coming from that.

Senator HICKENLOOPER. In the record we had yesterday, I believe Dr. Warren gave the tremendous amount of radiation activity there as compared to normal where these people have been living for no one knows how many generations. Perhaps those studies have not gone far enough to produce any results as yet.

It would seem to me that with that tremendous overplus of radiation exposure in this monazite sand area, we might get at least some significant data as to what had happened generation after generation there, if anything.

Dr. CROW. We might. On the other hand, we might not. I want to point out some of the difficulties in this kind of a study.

One is that the numbers of persons are fairly large, but they are not very large with respect to what is needed for this kind of study.

The second is that one always has some doubt when he compares one community with another community that there is not something else that is different about these two communities besides just the radiation. I think it is a difficult question.

Senator HICKENLOOPER. If we are attempting to pinpoint this for at least the purpose of these hearings on radiation, then I presume it would depend on whether there is reliable data going back a number of years or what the history of that situation is. From the evidence given yesterday that this is an area in the world where the strength of the radiation is many many times any possible radiation that might come from tests and is a number of times the radiation force of the normal background radiation on the average over the country or over the world, it would seem to me that would be a very fertile field for seeing whether mutations of significance have actually occurred there.

Dr. CROW. I certainly hope such a study will be done, but it has not been done.

Representative HOLIFIELD. Are there any further questions?

Representative COLE. Mr. Chairman, I just want to make sure my understanding of the doctor's figures is correct. That is, the figures which he placed on the blackboard.

Do those figures indicate that it is your very very rough guess that over the next generation of the 30 years of the total number of people in the world who will be born with a gross genetic disease, the number of stillbirths out of that total, 1 out of 10,000 of that gross number can be attributable to the presently produced radiation from fallout?

Dr. CROW. That is my best guess; yes. To clarify one point, I am assuming continuance for 30 years of the testing at the present rate.

Representative COLE. Based on what has occurred?

Dr. CROW. Based on the 5-year rate; yes.

Representative HOLIFIELD. These figures that you give us are based on the present rate of testing, and if that rate of testing would increase tenfold or more as it has in the past 10 years from the original rate of testing in 1946, then these figures would have to be multiplied, would they not, by the increased rate of testing? And would it be a simple multiplication or would it have more effect or less effect than the figures involved?

Dr. CROW. For all practical purposes it would be a simple multiplication. If testing were increased by tenfold each of my values here would increase by tenfold.

Representative HOLIFIELD. This is also assuming that the one-tenth roentgen is an average distribution.

Dr. CROW. Yes, sir.

Representative HOLIFIELD. If it is not average, as we have had testimony is that there is no such thing as an average distribution of fallout, but that the fallout is heavier in the temperate zone and it is uneven in the temperate zone, then there would be a higher degree of radiation received upon some groups of individuals than the one-tenth, would there not?

Dr. CROW. That is correct.

Representative HOLIFIELD. To that genetic strain possessed by those individuals, this would have to be multiplied at this time.

Dr. CROW. That is correct.

Representative HOLIFIELD. Assuming that they received a roentgen in certain areas, this would be a 10 times factor, would it not?

Dr. CROW. Yes.

Representative HOLIFIELD. And if they received 50 roentgens, it would be a 500 times factor?

Dr. CROW. Yes.

Representative HOLIFIELD. We do know that condition does exist in the world. There are peaks and valleys of distribution of fallout from the present testing rate.

Dr. CROW. Yes.

Representative HOLIFIELD. So in considering this average we should also consider the fact that it is an average and not an extreme either way, because there will be people who will receive no radiation from these tests.

Dr. CROW. Yes. I do want to say one thing, Mr. Chairman. Most of the harm from this will show up several generations in the future. By that time I suspect that within small areas the effects of peaks and valleys will in a sense have disappeared because persons from peak areas will have married descendants of persons from valley areas and the children will be mixed up by that time. On the other hand, if there are large differences in large areas, if one continent has a heavier distribution than another continent, most of the descendants of persons from one continent will stay in that continent. In this case the difference would be important.

Representative HOLIFIELD. I do not think we should leave this without pointing up that these figures again are based on peacetime testing and not upon the utilization of hundreds of weapons in a possible war.

Would you care at this time to say what you think would happen to the genetic pool of the human race if a hundred 5-megaton bombs were dropped upon any country in the world by any other nation in the world?

Dr. CROW. I have not made any such calculation, but my guess is that it would be disastrous.

Representative HOLIFIELD. That it would be disastrous?

Dr. CROW. Yes.

Representative HOLIFIELD. I am speaking about the survival. We know that a lot of strains would be eliminated immediately.

Dr. CROW. Yes.

Representative HOLIFIELD. To the survivors it would be disastrous as far as the future of mankind is concerned.

Dr. CROW. Yes. I think a major nuclear war would be a serious genetic hazard as well as a serious hazard immediately.

Representative HOLIFIELD. That is the point I wanted to bring out.

Dr. CROW. It may be, Mr. Chairman, that some of the people who will follow me have done some calculations on this point. I simply have not.

Representative VAN ZANDT. Dr. Crow, is this your best estimate?

Dr. CROW. Yes.

Representative VAN ZANDT. Have you taken into consideration the estimate of some of your colleagues in this highly specialized field?

Dr. CROW. Yes. Other people have made some of these same estimates. In particular the first estimate would agree with that one made by the National Academy of Sciences Committee.

Representative VAN ZANDT. Would you say your estimate is a general opinion of you and your colleagues?

Dr. CROW. I think so. You will have a chance to ask my colleagues later on.

Senator HICKENLOOPER. Dr. Crow, perhaps you have covered this, but have you discussed whether or not there are degrees of deleterious effects of mutations? In other words, would some mutations be by hazard or otherwise worse than others, or would some mutations merely result in a slight alteration that would in the long run be not very serious at all?

Dr. CROW. The answer is, I think, "Yes" and "No" to your two statements. Certainly mutations range from very serious to very mild. I did make the point earlier and I would like to repeat it now, that we cannot afford to ignore mild mutations because the milder mutations by virtue of being milder are less likely to cause the sterility or death of the person who possesses them and therefore more likely to persist in the population and therefore more likely to affect a larger number of persons.

So to some extent the mildness of the mutation is compensated for by the greater number of individuals it affects. For example this minor list I put at the bottom I do not regard as negligible at all. I think it may be the major part of the damage. It is so intangible that it is very difficult to measure or even to discuss.

Representative HOLIFIELD. Dr. Crow, I asked you a question a few minutes ago and it was not quite a fair question when I asked you about the number of weapons—one hundred 5-megaton weapons—so let me put it in a different way, which would possibly be more within your field of consideration.

If there was an accumulation of 500 roentgens over a period of 5 or 10 years by an average of the population, as might be expected from a massive attack such as I described, then would your answer be more explicit?

Dr. CROW. If I take the one-tenth of an r. figure that I have used here and convert that to 500 r., that means simply that every figure on this is multiplied by 5,000. I think it would be serious.

Representative VAN ZANDT. Dr. Crow, does this tear down the resistance in the body?

Dr. CROW. Yes.

Representative VAN ZANDT. I am thinking of the diseases spread over the world from time to time, like polio, and the virus situation in the Far East at the present time. Would it not add to the problem considerably from the standpoint of deaths?

Dr. CROW. Yes. I think what the nature of most genetic mutations is, as you said a few minutes ago, to lower the resistance so that the disease is more likely to be fatal than it would be otherwise.

Representative VAN ZANDT. Therefore we would be faced with additional hazards and other diseases that are taking a heavy toll today?

Dr. CROW. Yes.

Representative VAN ZANDT. It would greatly aggravate the problem.

Representative COLE. Before the doctor leaves, I am intrigued by his answer that 500 r. up in the atmosphere we would multiply all of his figures by 5,000. That would conclude that in the next 30 years, out of every 10,000 injurious effects on living persons or unborn persons, 5,000 would be due to 500 r. in the atmosphere.

Dr. CROW. One way of saying it is that I would expect that the number of such effects we now have would be increased by approximately 50 percent.

Representative COLE. What do you calculate would be the needed number of roentgens in the atmosphere to make the equation 10,000 equal 10,000? Would it be 10, or 100? It would be 1,000, would it not?

Dr. CROW. If I say one-tenth——

Representative COLE. If you say 1,000 r. is in the atmosphere then your fraction would be 10,000 out of 10,000 cases attributable to these 1,000 r.

Dr. CROW. I think that is right; 1,000 r. would, on these assumptions, about double the numbers for many generations in the future.

Representative COLE. That would be ten thousand times more radiation than presently exists?

Dr. CROW. Yes. Ten thousand times my assumed fallout level.

Representative HOLIFIELD. Thank you very much.

We are going to ask all of you gentlemen to remain until the end of today when we will have a roundtable discussion on this subject. We will do it at the end of the morning if we can. If any of the witnesses do have previous engagements they will be excused.

Our next witness is Dr. Bentley Glass. Dr. Glass is professor of biology at the Johns Hopkins University. He has a notable record. We are glad to have you with us.

STATEMENT OF DR. BENTLEY GLASS, PROFESSOR OF BIOLOGY, THE JOHNS HOPKINS UNIVERSITY [2]

Dr. GLASS. Mr. Chairman and members of the committee, like the preceding witness and those who will follow me this morning, I served as a member of the National Academy of Sciences Committee on the Genetic Effects of Radiation, and I would like to have it clear on the record that the opinions I express this morning are my own opinions and not those of the Committee as such, although I believe that the Committee would be in agreement with them.

[2] Department of biology, Johns Hopkins University, Baltimore, Md. Genetics. Born: Laichowfu, Shantung, China, January 17, 1906. A. B. Baylor, 1926; M. A., 1929; Ph. D. (genetics), Texas, 1932. Teacher, high school, Texas, 1926–28; teaching fellow, Baylor, 1928–29; National Research Council fellow, genetics, Oslo, Kaiser-Wilhelm Institute and Missouri, 1932–34; instructor, zoology, Stephens College, 1934–38; assistant professor biology, Goucher College, 1938–42; associate professor, 1942–46; professor, 1946–48; associate professor, Johns Hopkins, 1948–52; professor, 1952–; research associate, bureau of education, research in science, Teachers College, Columbia, 1936–37; Baltimore Rh blood typing laboratory, 1947–52; consultant, U. S. (From American Men of Science, 1955.)

I hope that what I have prepared to say will answer some of the questions that have already been raised by the members of the committee, if they have not already been adequately answered to your satisfaction.

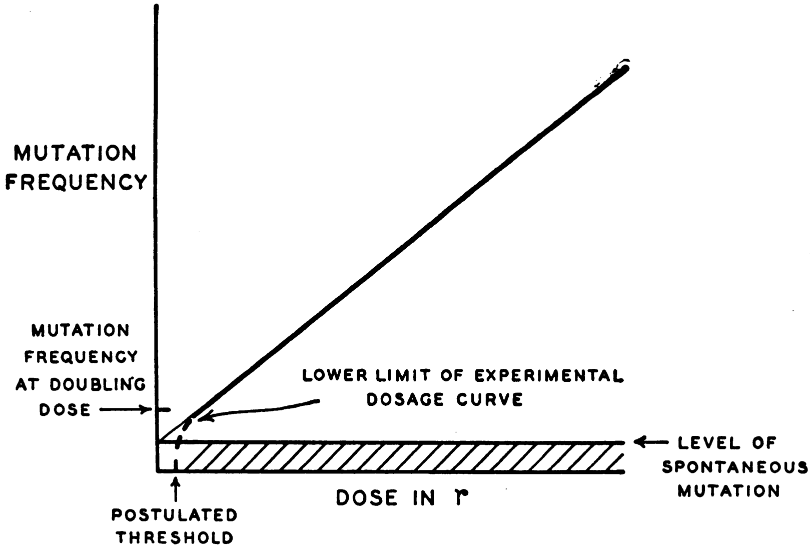
The hereditary material of all cells is located in bodies called chromosomes which are contained in the nuclei of the cells. This material is divisible into genes, perhaps 10,000, 20,000, or even 40,000 in each cell. This explains why—as I believe, Senator Hickenlooper asked—the matter that a large proportion of ova are not fertilized is not really a matter of prime concern, since we are concerned with the probability of mutation of the individual gene and there are so many of these in each cell that the probability that a mutation of some one of those genes will occur after any sizable dose of radiation is considerable. There would hardly be an ovum or a sperm cell that would not carry a mutation of some gene or other if the dose of radiation were more than a few roentgens.

Each of these genes regulates one important biochemical step in the living machinery, or controls some other significant property of protoplasm. The biochemical nature of the material is now identified as being deoxyribose nucleic acid (DNA), which forms a major part of the chromosomes. Permanent genetic changes, that is to say, mutations, consist then of modifications of the chromosomes and specifically of the DNA.

The hereditary material not only regulates the synthesis of enzymes and thus controls all life processes extrinsic to itself; it also has the unique ability to duplicate itself so that every new cell coming into existence has a replica of the genes and chromosomes of the parent cell. This at once explains why on the one hand damage done to other parts of cells can, if not too extensive, be repaired by replacing the lost or damaged machinery with newly synthesized parts, but on the contrary damage to the genes and chromosomes is irreparable. Such damage constitutes a defacement of the mold, the model, the die by means of which the new hereditary stuff is replicated, and which therefore inevitably bears the replica of every flaw in the original. Only by an exact reverse mutation may the damage done to the hereditary material by a mutation be erased. As long as it is transmitted in heredity to offspring it is permanent.

Microscopically visible fractures of chromosomes are produced by all sorts of ionizing radiations. In general, only those alterations that involve two or more breaks of chromosomes in the same nucleus, followed by reunions in new arrangements, can be inherited, for single breaks result in losses which are promptly fatal. Hence these gross mutations increase as the square or some higher power of the radiation dose.

I would like to duplicate a graph that Professor Pollard presented to the committee yesterday, plotting dose against mutations produced. We might elaborate on his diagram a bit by putting in a kind of a substratum to represent the level of spontaneous mutation. I draw it all the way across, since no matter how much of a dose of manmade radiation is applied, this would be the proportion of spontaneous mutations.



Now the gross chromosomal mutations which are microscopically visible show an increase with dosage like that first curve which Professor Pollard drew for you. These gross mutations are generally very harmful but because they occur mostly only at high doses and chiefly in spermatozoa—rather than ova—which may be eliminated if the male is rendered temporarily sterile by the high dose of the radiation, they are not very significant in the overall picture of mutation and the damage that mutation does.

Of chief importance are the so-called point mutations, in which the lesions in the hereditary material are submicroscopical in size. These increase characteristically in direct, linear proportion to the dosage, and, like the gross mutations are producible by all ionizing radiations, such as cosmic rays, gamma rays, and X-rays, and by ionizing particles such as beta particles, alpha particles, and neutrons.

These are the mutations, then, that show a linear proportionality to dosage even up to a very high dosage in all the organisms that have been studied experimentally. And although we cannot work on this region where the dose is very small the direction of that dosage curve points to this level of spontaneous mutation as its origin, which implies that even down to the very smallest doses each quantum of radiation is capable of producing a mutation.

As Professor Pollard said, it would be very difficult on any kind of physical ground to suppose that a threshold exists, say, at this level of radiation, (see figure) and you had a steeper slope to the curve right in this low dosage range than anywhere else.

Representative HOLIFIELD. Doctor, at that point, will you tell us where the amount of the dose begins in terms of roentgens?

Dr. GLASS. Yes.

Representative HOLIFIELD. I mean the amount of discernible calculation which you have in your linear field.

Dr. GLASS. The data are most extensive for the fruitfly and the lowest dose that has actually been studied is 25 r.

Representative HOLIFIELD. But the fruitfly is not as susceptible as the mammal.

Dr. GLASS. No, that is correct.

Representative HOLIFIELD. So you would have to raise that for the mouse or the man, would you not?

Senator ANDERSON. It would be lowered.

Dr. GLASS. The only part of the curve which has actually been studied—I think Dr. Russell will testify about this—is the range between 300 and 600 roentgens in the mouse. But in some plants and in bacterial studies part of this curve has been extended down to 5 roentgens or thereabouts.

Representative HOLIFIELD. In my previous question I should have said a lower dose, because I knew it took more to affect the fruitfly.

Dr. GLASS. Yes.

Because the changes in the genes are irreparable except by exact reverse mutations, the effects of doses of radiation administered at different time are cumulative; that is to say, the mutation rate is proportional to the total dose administered, irrespective of whether it is given in small doses over a long period of time or in large doses of high intensity as in the case of X-rays.

Because a mutation can be produced by a single ionization in the right place, there is no threshold below which the amount of radiation is too small to produce mutations—that is, every dose produces mutations with a probability equal to its magnitude.

This is to repeat what Dr. Crow said, that there is no safe dose of mutation. This curve continues down without any threshold until it hits the zero point at the level of the spontaneous mutation in the population. Because the genes control important, often essential biochemical steps in the living system, a mutation of any one of them is practically always harmful, and would often be lethal, were it not that each cell, being lineally descended from the union of sperm and egg at the beginning of the individual life, has two representatives of each gene, the one maternal in origin and the other paternal. We have a kind of life insurance, so to speak. Two genes of every sort, so that if something goes wrong with one of them we can still carry on. This is very important to us. It is why most of the mutations that are produced, although they would be very harmful if we had 2 doses of them, have a much milder effect when we have only 1 mutation of that kind.

Thus a mutation is often not obviously harmful at once, unless its effect is dominant over the normal gene of the same sort which is still present. But the recessive mutations are nonetheless harmful, and in many cases kill or severely handicap those persons in the population who eventually happen to inherit the same mutation from both parents. This may occur only after many generations—as Dr. Crow said, 30 or 50 generations—have elapsed since the mutation originated. Consequently, harmful mutations can accumulate and be carried in a population without visible damage until at length an equilibrium is reached at a frequency where the mutation rate that produces each particular kind of harmful gene is balanced against the elimination of that gene from the population either by the death or by the failure to reproduce of some person who gets a double dose of the gene.

There is also evidence that even in single dose most mutant genes do harm, although it is of an intangible sort, affecting general resistance, shortening the life span, or reducing the fertility of its carrier. I think Dr. Crow has spoken sufficiently to that point. From studies on the fruitfly, which are the only ones on any animal sufficiently extensive, it appears—and I believe these are the figures you were asking for a while ago—that about one-fourth of all mutations are lethal or semilethal, 15 to 20 percent produce sterility in one or both sexes, and nearly all of the remainder, whether producing visible changes or not, reduce the vitality. Less than 1 in 100 mutations—probably nearer 1 in 1,000—is definitely advantageous under existing conditions, although some of the subvital ones might become neutral or even advantageous under altered circumstances.

Two other things I would like to emphasize. First—and this is an important point which I have not seen previously emphasized in these hearings—most, if not all, of the mutations produced by radiation act as if they were truly losses of a part of the hereditary material. Some of these losses are big enough to see in the microscope. Others cannot be seen, but are probably losses, because they cannot be made to revert to the original condition. For this reason, mutations produced by radiation are probably as a class much worse in nature than those which arise spontaneously.

Secondly, there is no known way of directing mutation and of producing mutations of just the particular gene, a mutation of which may be desired. Suppose there is one mutation in a thousand that is beneficial. We cannot produce just the mutation of that one sort we desire. We have to produce a thousand mutations and pick it out. Radiation acts blindly, and that is why the deleterious nature of the vast majority of mutations is so important. By means of several hundred r. of radiation, it might indeed be possible to increase the probability of obtaining a desirable mutation in a spermatazoa or egg cell to a chance of 1 per 1,000. At the same time, the probability of getting a lethal mutation of some gene would have risen to 1 in 4, and the probability of getting a mutation with some degree of harmful effect would have become a virtual certainty. That is why we must wait for the slow processes of evolution to sort out the advantageous changes.

The breeder, of course, can produce the advantageous mutations along with the many deleterious ones and discard the latter. But in the human population we cannot do that.

It would be a grave mistake to think that mutations of the hereditary material are confined to the reproductive cells or germ line. They can unquestionably occur also in the somatic cells of any tissue—kidney, brain, liver, skin, everywhere—but at present we have too little knowledge of what consequences may follow. In case the mutations are recessive, perhaps little damage would result because of that insurance principle I spoke of.

More significant would be dominant or partially dominant effects upon essential metabolic or biochemical processes, which might as a result be impaired. The loss of damaged cells would presumably do little harm, since in most tissues undamaged cells could take their places and repair would follow. But recent suggestions made here yesterday that leukemia and shortening of the life span, when induced by radiation, may increase linearly with the dose and show

no sign of a threshold at the lower dosage rate, may imply that those effects, too, result from the induction of mutations by radiation, and their accumulation in the somatic cells.

I know that Dr. Lewis would not commit himself to that point of view, but I think he and others would agree that this is a possibility that must be recognized. Possibly cancer, in general, may arise through the same cumulative effect, which does not at all exclude the intervention of other types of agents (viruses, nutritive factors, or chemical agents) in the final outburst of malignancy.

I just want to emphasize here that contrary to what many people seem to think, mutations are not limited to the reproductive cells. They can occur to any part of the body. If they are damaging in the reproductive cells we would suppose that they were damaging in the other cells, too. It is only because the body has the ability to replace damaged cells that we can escape some of these effects.

I shall now try to appraise the current exposure of the United States population to nuclear radiations, with special reference to fallout. According to the views of most, though not all geneticists, the genetic effects of exposure to radiations can best be weighed in relation to the magnitude of the spontaneous mutation rate, which is currently responsible for a certain amount of tangible genetic defect in the population, and a certain load of wholly or partially hidden mutations in individuals who carry only a single does of any particular mutant gene.

If one could confidently assume that all spontaneous mutation was attributable to the background radiation of the environment, the problem would be fairly simple. Unfortunately, this cannot be done, since in most organisms the spontaneous mutation rate is demonstrably higher than could possibly be caused by the background. Many years ago Professor Muller, who may want to speak to this point later, pointed out that for the fruitfly not more than about one-thousandth of the spontaneous mutation could possibly be caused by the background radiation. For longer-lived animals a greater fraction may well be due to the background, since the overall mutation rate per generation in different species holds fairly constant, that is, within about one order of magnitude—10 times, say—although the exposure to background radiation increases far more than that, enormously, with length of life.

If the low-level radiation of the background in fact causes a proportionate amount of mutation, then in a species that lives a thousand times as long as the fruitfly all the spontaneous mutation would be caused by the background, and some eminent geneticists have argued that that is the case. Man lives about 365 times as long as the fruitfly, for their reproductive lifetimes are of the order of 30 days and 30 years, respectively. Thus, while it may not be very likely that for man the "doubling dose of radiation"—that is, as Dr. Crow defined it, the dose that would double the total spontaneous mutation frequency, is as small as the amount of the background radiation, it is quite possible that it may be no greater than 3 times the background, or about 10 r. The doubling dose is the dose that would raise the level of spontaneous mutation in my figure to just twice the original level. Here would be the mutation frequency caused by a doubling dose, and the doubling dose would be the corresponding dose right here [indicating

on the blackboard], that would lift the spontaneous mutation frequency to a level just twice as high.

Representative COLE. Doctor, while you are at your diagram, I do not understand why your linear line does not start at the corner of your chart, rather than upward, since there are mutations which occur from spontaneous radiation.

Dr. GLASS. Yes; it starts from the level of spontaneous mutation. This becomes effectively the corner right here. At all doses there is a certain fixed proportion of spontaneous mutation.

Representative COLE. You and Dr. Crow said that there are mutations resulting from spontaneous causes.

Dr. GLASS. Yes. Those are the mutations that are indicated in this blocked-in part at the floor of the diagram.

Representative COLE. But your diagram would indicate that mutations occur only from induced radiation and not from spontaneous.

Dr. GLASS. No; only that all mutations due to extra radiation are proportional to the added dose of radiation. For example, let us say the doubling dose represents 40 roentgens. At 40 roentgens the percentage of mutations below the horizontal line is the spontaneous frequency, and from that level up to this level is the frequency induced by the radiation. So at every dose—at large doses as well as at low doses—to the frequency of mutations induced by the radiation there must be added a small percentage of mutations that is occurring spontaneously in the population.

Senator BRICKER. Are there any data, Doctor, showing that the ratio of mutations due to background radiation is twice as much at Denver as it is at Washington, D. C.?

Dr. GLASS. No. I believe no data of that kind exist.

Senator BRICKER. You would naturally conclude that the rate would be higher?

Dr. GLASS. The increase in radiation at Denver is, of course, very small. Studies were done many years ago in an effort to see whether cosmic radiation, which is greater in amount at high elevations above sea level, produces a proportional amount of mutation. Fruitflies were placed on top of Pikes Peak and compared with fruitflies kept at sea level. This was a very large and laborious experiment, but it never added up to anything conclusive, because the difference in the amount of cosmic radiation at sea level and on top of Pikes Peak is so low in terms of roentgen units over a short period of time that you just would not get any perceptible change in the percentage of mutations.

Perhaps if the experiment could have been done with bacteria where you could work with much larger numbers, the effect could have been demonstrated. But certainly for the human population I know of no evidence at all that would show that the mutation rate varies with altitude.

Representative COLE. Doctor, would you indicate on your chart where the zero dose of radiation would occur?

Dr. GLASS. Manmade radiation? Zero would be right here [indicating on blackboard the level of spontaneous mutation].

Representative COLE. I was wondering about zero rate of radiation irrespective of source, whether spontaneous or induced, since radiation you have said does cause mutation. Therefore, mutation starts with

the occurrence of radiation. Would you indicate on your chart where is the zero of radiation irrespective of source?

Dr. GLASS. It is on this axis (the ordinate) at this particular point [indicating the intersection of the level of spontaneous mutation with the ordinate].

Representative COLE. Where is the zero mutation frequency?

Dr. GLASS. The zero mutation frequency would be at the bottom of the figure.

Representative HOLIFIELD. From radiation but not from other effects.

Dr. GLASS. From any source whatever. The zero mutation from added radiation would be approximately here [indicating the spontaneous mutation level]. It might be a little below that.

Representative COLE. Put a circle there so I can see it. Zero mutation frequency.

Dr. GLASS. Zero mutation frequency is right here.

Representative COLE. And zero radiation is there also?

Dr. GLASS. Yes.

Representative COLE. Including spontaneous radiation.

Dr. GLASS. Yes. I think the thing that is troubling is that perhaps if a sizable part of this spontaneous mutation frequency is due to background radiation, then the point at which this curve should be projected is not right here [intersection of ordinate at the level of spontaneous mutation] but at some point between the bottom and the spontaneous mutation level, at a point which corresponds to the proportion of the spontaneous mutation produced by radiation. If that is only one-thousandth of this spontaneous amount, as it is in the fruitfly, then it is so close to this point of origin that I could not draw it separately on the graph. If, on the other hand, as may be in the human species, according to Haldane's argument, perhaps all, or at least a third of the spontaneous mutation was produced by the background radiation, then the dosage curve would not point at that origin on the spontaneous mutation level, but would point at a lower origin. But we do not have the data for human population, only data from the experiments on animals.

Representative COLE. Thank you, Doctor.

Dr. GLASS. It is quite possible, then, that the amount of the doubling dose may be no more than 3 times the background or about 10 roentgens—that is, on the basis of the argument that the reproductive lifetime of man is about 365 times as long as that of the fruitfly and that a proportionally larger amount of radiation is received during that lifetime.

I have left out of this account the probability that the human genes are more sensitive to radiation than the fruitfly genes. At least we can base the argument on the analogy with the genes of the mouse. The mouse genes seem to be more sensitive to radiation than the fruitfly genes and therefore, if that should apply to human genes, it would also work toward an effective lowering of the doubling dose, the dose of radiation that would double the spontaneous radiation rate.

In the most recent estimate made by the consultants of the National Academy of Sciences committee—Drs. John Laughlin and Ira Pullman have estimated the average exposure of the population of the United States to background radiation as amounting to a dose to the reproductive organs over a 30-year period of 3.1 rem. (Cosmic radia-

tion, 0.78 r.; earth and housing, 1.59 r.; atmospheric radioactivity, 0.06 r.; internal radioactivity, mainly the beta radiation from potassium-40, 0.69 r.)

To correct something that was said yesterday, according to their data the amount from earth and housing is about double that from the cosmic radiation. This is one of the things that makes the experimental answer to the question that was posed a moment ago about the effects of cosmic rays on the mutation rate a very difficult one to work out experimentally. As Dr. Crow said, the lowest conceivable doubling dose would be 3.1 r. to the gonads over a period of 30 years.

Three times the average background would amount roughly to 10 roentgens, which is the permissible limit for the general population recommended by the National Academy Committee last year. A more probable range for the doubling dose is 30 to 50 r., but that expectation, which was adopted by both the American and the British committees reporting last year, is based on experimental evidence from fruitflies and mice, which have much shorter reproductive lives than human beings. That assumption, I feel, may not be sound.

Preliminary studies in my own laboratory with normal human cells growing in tissue culture—cells derived from kidney—and exposed to radiation of X-rays, indicate that doses of even 50 or 25 r. produce significant increases in the number of microscopically visible—gross—chromosome mutations, and from that fact it may be deduced that an even greater increase of submicroscopic mutations is to be expected.

These preliminary studies make me wonder whether our committee last year was not oversanguine in estimating that the 10 r. permissible level we recommended amounted to no more than one-third or one-fourth of the doubling dose. If it should actually constitute a doubling dose, then geneticists will certainly want to reconsider all their recommendations. For a doubling dose means that, after a lapse of generations, the frequency of all kinds of hereditary defects in the population will be doubled.

Right now this frequency amounts to at least half of all tangible defects not caused by accident or infectious disease. For example, about 5 percent of births are marked by some congenital defect, and at least 2 percent of these, according to the estimate of the National Academy Committee, are of a simple hereditary nature. Doubling just these, to say nothing of those less hereditary defects which Dr. Crow has emphasized, and those that arise later in life, would mean eventually about 2 million more defective babies per generation than now, assuming a hundred million babies per generation in the United States.

The 30-year gonadal dose from fallout amounts, according to our estimates, to about one-tenth roentgen if extrapolated on the basis of the average fallout for the past 5 years, or two-tenths roentgens at the rate of testing during the 2 most active years in that period. This is small indeed compared to the estimated background radiation or to the amount received on the average from medical and dental diagnosis and therapeutic uses of X-rays, radium, and radioisotopes, which amount to about 4.6 r. reproductive dose during a 30-year reproductive lifetime.

A safety factor here—that is, in relation to fallout—is the very fact that strontium 90 is accumulated in bones and radioiodine in the thy-

roid, and consequently they provide only a negligible amount of radiation to the gonads. We are not so sure about the localization of cesium 137, however. Nonetheless, if the gonadal dose from fallout which constitutes the genetic hazard is at the present time only 1 or 2 percent of the permissible limit for the general population, that is no reason to be complacent, in my opinion, about its rise. The increasing tempo of weapons-testing in 1957 will certainly make a reevaluation necessary.

Senator BRICKER. Is the half life of cesium 137 the same as strontium 90.

Dr. GLASS. Yes, sir, about 30 years.

Representative HOLIFIELD. It is deposited in the muscles.

Dr. GLASS. Yes, in the muscles and soft tissues, generally. It is possible that it might even concentrate in the reproductive organs. This is something that I think should be very urgently looked into in our experimental studies. I have heard a rumor to that effect. That is all I can say.

Representative HOLIFIELD. Is the power of emissions stronger than the strontium 90?

Dr. GLASS. I think it is about the same. I am not certain.

Representative VAN ZANDT. Doctor Glass, this increased tempo of weapons testing in 1957, did take into consideration the British testing?

Dr. GLASS. That is what I mean, the British and Russian testing plus our own.

Representative VAN ZANDT. Looking to 1958 and 1959, did you include any other nations participating in these tests?

Dr. GLASS. No, I do not know that any other nation is ready to begin weapons-testing, but I think that unless some international agreement to limit weapons-testing, or to eliminate it, is reached, it will be only a matter of a few years until other nations will be testing weapons, too.

Representative VAN ZANDT. In 1958–59 do you anticipate that the tempo of the schedule of 1957 tests will be stepped up?

Dr. GLASS. I certainly do, unless we can reach some international agreement.

Representative VAN ZANDT. In other words, you anticipate an annual increase of tests.

Dr. GLASS. Yes.

Senator BRICKER. The Russian tests up to the present produced about one third of the total of radiation effects through fallout.

Dr. GLASS. Others can speak about that better than I. I think that is about the correct fraction.

I must emphasize, too, that because I estimate fallout to be at present a negligible hazard to the genes we must pass on to future generations, in comparison with other factors, I by no means feel that the accumulation of strontium 90 is a negligible hazard in other respects. The evidence that has been presented to this committee would make me think otherwise. These are simply two different questions, and I am speaking to the genetic question only.

When we consider that at present our population is receiving almost half of the 10-roentgen allowance per generation from manmade sources, and that exposure is certain to increase as wastes from the development of peaceful uses of atomic energy multiply, a fivefold in-

crease in fallout from weapons testing would add to a grave problem.

There are clearly many uncertainties in the evaluation of these questions. I would therefore like to conclude by stressing something said in the final part of our National Academy of Sciences Committee report.

> The present state of advance in atomic and nuclear physics on the one hand, and in genetics on the other hand, is seriously out of balance. We badly need to know much more about genetics * * *

There are critical problems in this area about which answers are urgently needed, for example, the exact magnitude of the doubling dose.

> Our society should take prompt steps to see to it that the support of research in genetics is substantially expanded, and that it is stabilized.

I think that this remark, which I had prepared before I heard Dr. Pollard yesterday, strongly reinforces what he said to the committee.

The program of the Atomic Energy Commission exemplifies this unbalance between emphasis on the physical aspects of atomic energy and on the biological counterpart, its effects on living beings. Without wishing in any way to reflect on the competence within their own fields of our sincere and able Atomic Energy Commissioners, I think it safe to predict that this unbalance is likely to continue until the genetic and other biomedical problems and points of view are appropriately represented on the Commission itself.

Representative HOLIFIELD. Would you not say that a more desirable goal would be to have a completely independent study of this made, so that there would be no justification on the part of those making the study to attempt by the results of their study to justify an administrative policy which may or may no be correct?

Dr. GLASS. That is an interesting question, Mr. Chairman. I would say that, in my own personal opinion, if at the beginning it had been set up that way, I would answer yes. But we have a going concern, and the Atomic Energy Commission has a large program of support for research in the biological sciences at the present time. I have indicated that I don't think it is by any means adequate, but it is large. I have great fear that if there was some attempt to shift all of the biological, genetic, and medical support of research in the atomic energy area to some other agency, there would be such disruption and chaos for a period of several years, that we would lag sadly, even more than now, in our program.

Representative HOLIFIELD. Any attempt that could be made within the program to achieve complete independence by freeing of such an advisory group or research group from administrative policy would be desirable, would it not?

Dr. GLASS. Yes, I think so.

Representative HOLIFIELD. We had an Advisory Committee on Reactor Safeguards.

Dr. GLASS. Yes.

Representative HOLIFIELD. In one instance their advice was not taken, and this is the problem that you run into with all advisory groups, that is, that their advice sometimes is not taken. I am not saying that it should be taken at all times. It should be considered in relation to the other problems which the administrator has. That is why I bring up the question.

Representative COLE. On that point, is it not true that Dr. Glass himself is a member of the Advisory Committee?

Dr. GLASS. I am a member of the Advisory Committee to the Division of Biology and Medicine of the AEC, yes.

Representative COLE. With further reference to your feeling that the program of the Commission is out of balance, it was indicated to me that the effort of the Commission in the field of biology and biological aspects of atomic energy has been neglected. I do not think you intend to imply that, do you?

Dr. GLASS. No, not neglected in an absolute sense. It is a matter of emphasis. It is a relative balance that is important.

Representative COLE. Since you are on the Advisory Committee in this field, while dollars are not a true yardstick in determining the degree of effort, could you tell us the amount which the Commission is spending annually in this field in which you think there should be greater emphasis?

Dr. GLASS. I will have to rely on my memory here. I believe it is currently around $38 million. Dr. Dunham is here.

Representative HOLIFIELD. Dr. Dunham, could you respond to the question?

Dr. DUNHAM. The question was the overall biology and medicine budget. About $31 million.

Representative COLE. That represents an effort on the part of how many individuals? I am speaking of scientists.

Dr. GLASS. I am afraid I cannot answer that.

Dr. DUNHAM. This material will be available to you by tonight. We are trying to figure that out. It is very difficult to sort out the projects and add up the number of scientific man-years.

Representative COLE. I was going to say it is my recollection, Dr. Dunham, at the beginning of these hearings you indicated of the order of 500 individuals were engaged in this research.

Dr. DUNHAM. I think it is a considerably higher figure now that we have gone back and looked at the record. We will have this for you.

Senator BRICKER. Most of this work is done by contract with the various universities and research centers.

Dr. DUNHAM. It is by contract with universities, independent laboratories and with our national laboratories.

Senator BRICKER. It would be practically impossible to know exactly the number of scientists working in the various fields, because this is determined by the local organizations.

Dr. DUNHAM. It is very difficult because you get people working part time on these projects. It will be an educated guess at best as to the figure we will come up with.

Senator ANDERSON. Did you say that the general overall biology and medical budget was $31 million?

Dr. DUNHAM. That is correct.

Senator ANDERSON. That includes a whole lot of things besides genetics.

Dr. DUNHAM. That is correct, sir.

Senator ANDERSON. Could you give us any idea when you give us a report how much money is being spent to study this question of genetics which has interested Dr. Glass and so greatly interested a great many people in the United States?

Dr. DUNHAM. This figure will be broken out separately.

Senator ANDERSON. At the same time, have you any idea how much the Atomic Energy Commission is spending in research in physics?

Dr. DUNHAM. I do not recall their exact budget this year, but it is in the $40 million or $50 million range.

(NOTE.—This figure was later checked by Dr. Dunham, and the budget for current fiscal year for the Research Division is $59,523,000 excluding cost of equipment.)

Senator ANDERSON. They are spending that much on a few reactors alone.

Dr. DUNHAM. Very definitely so. That is in a different part of the budget.

Senator ANDERSON. So we have plenty of money to find out how a reactor is going to react, but we do not have too much money to find out about genetics.

Dr. DUNHAM. It is one way to look at it.

Senator ANDERSON. It is a way that a great many mothers and fathers and even some grandfathers are interested in looking at it.

Representative VAN ZANDT. Dr. Glass, you say "appropriately represented on the Commission itself." What are your recommendations?

Dr. GLASS. I would say that the balance might be restored, possibly adequately, by one representative of the biological sciences. Perhaps a geneticist, perhaps not.

Representative VAN ZANDT. Serving as an AEC Commissioner?

Dr. GLASS. Serving as a Commissioner. I would also like to see either the present Advisory Committee to the Division of Biology and Medicine serving as a general advisory committee to the Atomic Energy Commissioners, or else I would like to see the present General Advisory Committee revised to include geneticists and biologists.

Representative VAN ZANDT. At any time during the past several years, have you made these recommendations to the Commission?

Dr. GLASS. No; I have not.

Representative HOLIFIELD. Dr. Dunham is asking for permission to speak.

Dr. DUNHAM. I would like to state that the Advisory Committee on Biology and Medicine is advisory to the Commission, and it was so established by the first Chairman of the Atomic Energy Commission.

Representative HOLIFIELD. But it does not have a geneticist or biologist on it.

Dr. DUNHAM. No. The Advisory Committee on Biology and Medicine, of which Dr. Glass is a member, is advisory to the Commission, not just to the Division of Biology and Medicine.

Dr. GLASS. This is technically correct. At the same time I think it is correct, is it not, Dr. Dunham, to say that it has a ranking somewhat lower than that of the General Advisory Committee?

Dr. DUNHAM. It is different in that the exchange of correspondence between Mr. Lilienthal and the Academy at the time the committee was set up indicated a definite wish that it be the advisory group on all biomedical problems to the Commission.

Representative COLE. That would indicate that there is no biologist on the General Advisory Committee.

Dr. DUNHAM. That is correct.

Representative COLE. But there is a special committee whose responsibility is exclusively in the field of biology.

Dr. DUNHAM. That is correct.

Representative VAN ZANDT. Mr. Chairman, may I ask Dr. Glass this question? Just what advantages would be enjoyed if we had a biologist sitting as a Commissioner on the Atomic Energy Commission?

Dr. GLASS. May I read my last three sentences which I think perhaps answer that?

Representative VAN ZANDT. All right.

Dr. GLASS. The geneticist cannot help feeling frustrated when physical scientists, religious leaders, and common people everywhere raise a loud outcry for some answer to their fears of genocide by radiation, and at the same time the available funds for research are actually in danger of reduction. Some of the research required is expensive, but in comparison with the cost of a bevatron for physical research or a nuclear reactor in the program it is of course minor. It is vital to redress the balance.

Senator ANDERSON. You say you have been on this Advisory Committee. How long have you been on it?

Dr. GLASS. Two years.

Senator ANDERSON. Dr. Dunham pointed out this is an advisory committee directly to the Atomic Energy Commission. In those 2 years, how many times have you been called before the Atomic Energy Commission to give a report of what the Advisory Committee had been doing?

Dr. GLASS. There has never been any formal call before the Commission as a whole.

Senator ANDERSON. Have you ever been called into a meeting to discuss this directly with the Atomic Energy Commission?

Dr. GLASS. Not personally, no. There have been occasions when various Commissioners—Admiral Strauss, Dr. Libby, Mr. Murray, and I remember Dr. von Neumann, too, before he became too ill—sat in with our committee for one or more sessions as individuals. I do not believe there was ever a time when more than one of them was present at the same time.

Senator ANDERSON. I thought Dr. Dunham made quite a point that this is an Advisory Committee which reports directly to the Commission. How many times have you been in with the Commission for the discussion of this problem in which so many people are interested? None at all?

Dr. GLASS. None at all.

Senator HICKENLOOPER. Have you made reports to the Commission from time to time periodically as to your recommendations and findings?

Dr. GLASS. Yes. This is what I wanted to state. Our minutes, our conclusions and recommendations are always submitted to the Atomic Energy Commissioners in writing. A full report is made and often special letters by way of report are made. This has not been neglected.

Representative COLE. How does your committee operate? Is it by meetings of individuals or by exchange of views by paper?

Dr. GLASS. By meetings. We meet regularly.

Representative COLE. During the past 2 years how many times has your committee met?

Dr. GLASS. About 12 times.

Representative COLE. That would indicate once every 3 months.

Dr. GLASS. Every 2 months, except for the summer, when we sometimes skip a meeting. There are special meetings called fairly frequently, too.

Representative VAN ZANDT. Dr. Glass, you have recommended to this committee that a biologist be appointed to the Atomic Energy Commission. Would you go a step further and recommend to President Eisenhower that one of the vacancies that exist now as far as the Commission is concerned be filled by a biologist?

Dr. GLASS. This is my personal feeling of what is wise.

Senator ANDERSON. If you get as far with your recommendation as a majority of this committee got with its suggestion, you will not get very far.

Dr. GLASS. There is no harm in trying.

Senator HICKENLOOPER. May I ask Dr. Glass if he would recommend that a physician or a medical doctor be appointed to the Commission, and if he would recommend that a physicist be appointed to the Commission? Where do we stop? One of the difficulties is that when 1 very important branch of this very ramified science is appointed to the Commission, it has a tendency to create a little friction on some of the other equally important branches involved, and there are only 5 Commissioners. So while it is desirable to have the best scientific competence available in one way or another to the Commission, I believe it was the theory of the original act that the General Advisory Committee and the other advisory groups would bring the professional competence in substantial numbers in the various fields for the benefit of the Commissioners, and it would to some extent stop the friction which occasionally unfortunately may exist between the various branches as to their relative importance. So if one starts putting one branch representative on the Commission there will literally be no stopping within any reasonable numbers as to the other branches of this science which might feel they too were equally justified in having representation.

Dr. GLASS. I realize, of course, that one cannot have representation of all the sciences and the specialized branches. I do think, however, that the biological considerations here are so important and require such urgent attention that it is advisable that the Atomic Energy Commission include at least 1 physical scientist and 1 biological scientist.

Senator ANDERSON. Doctor, the fact that there is a great deal of discussion in Japan over the testing of British bombs right now, and that the British consulate has been subjected to a little activity by students in the past few days, would indicate that there is some interest in these biological effects of the bomb, would it not?

Dr. GLASS. It certainly would.

Senator ANDERSON. And the fact that 2,000 scientists have joined in suggesting that there are some biological ramifications to this story would suggest that this is an extremely important facet. We have representation of fine men from industry on the Commission who are greatly interested in the reactor program. I think it is fine that there may be people interested in that field. One of the things which touches the hearts of the people has been the possibility that this might have some future implications for our children, and our children's children, and on down through succeeding generations. Is not that the consideration that prompts your suggestion?

Dr. GLASS. It certainly is.

Chairman DURHAM. Dr. Glass, is any substantial amount of research being carried on by any other group except the Commission at the present time in the field of genetics?

Dr. GLASS. Yes, indeed. There are considerable numbers of projects in this area which are supported by research grants from the National Science Foundation and also from the National Institutes of Health. There are some, not too many, I think, which are supported by the Office of Naval Research, because their interest is mainly physiological.

Chairman DURHAM. I thought that was true and that is why I asked the question. Could you hazard a guess as to the amount of money being spent by those outside of the Commission at the present time?

Dr. GLASS. Very roughly, I would say at the present time the Atomic Energy Commission and its Division of Biology and Medicine is supporting about half the work that is receiving governmental support in genetics. It may be even more than that.

Chairman DURHAM. Would that particularly apply to radiation?

Dr. GLASS. Much of the genetic work that is supported by the National Science Foundation of the National Institutes of Health is not concerned with radiation. If you limit it to radiation genetics, I would say that the Atomic Energy Commission is supporting at least 90 percent.

Senator HICKENLOOPER. I just wanted to ask Dr. Glass this question about the availability of competent personnel. Is there a substantial reservoir of competently trained personnel in genetics that could use greatly stepped up amounts of money over and above what is being used in total or that is devoting its time total in the country in both private and public activity?

Dr. GLASS. I think it would be a mistake to try to triple or quadruple the amount going into this area in one year or overnight. But over a period of years, a stepped-up increase could be absorbed. Perhaps the principal difficulty at the present time is in the selection and training of adequate young people in this area. They are not being attracted into it in large enough numbers because of lack of support.

Senator HICKENLOOPER. In order to get down to specific cases, suppose the Atomic Energy Commission said today we will double the amount for the next year for genetics activity; would that have a significant effect in the immediate future, or would it take a substantial period of time before you could train the personnel and get the equipment and so on to utilize that extra money? Are they available in the United States at the present time?

Dr. GLASS. It would take a rather careful survey, I believe, to answer that question precisely. I am not sure that doubling it in 1 year would be at all advisable. But there are certainly some large programs which would require a large annual budget which could be initiated then and that now cannot be attempted. I believe that an increase by 50 percent could probably be absorbed in 1 year.

Senator BRICKER. Is it not true that there are many, many programs beyond those which are being conducted by the Government, either by the Atomic Energy Commission or defense research or the National Science Foundation, by private institutions in the various universities of the country?

Dr. GLASS. There is a lot of genetics of that kind going on, yes. As I said a moment ago, I believe about 90 percent of the genetic

problems relating to radiation effects is being supported by the Atomic Energy Commission.

Representative COLE. Mr. Chairman, in response to a question by Senator Anderson, Dr. Glass indicated that these activities in Japan at the British Embassy indicated an interest by the Japanese people in the biomedical aspects of the weapons testing. Similar activities occurred at the American consulate 1 or 2 weeks ago. If that was the interest which inspired these people to become active at those two consulates, why have they been silent with respect to the testing by the Russians?

Dr. GLASS. I do not know that they have been silent. Have they?

Representative COLE. So far as I am aware, there has been no appreciable degree of representation in front of the Russian Embassy in Tokyo as there has been with the American and British.

Dr. GLASS. That may be true. I know that at the time of the last Russian tests, when fallout occurred over Japan, there was a considerable stir and a good deal of reporting of the Japanese concern about this in our newspapers. I do not know that it took the form of a vocal demonstration.

Representative COLE. There must be some other motiviation on the part of the Japanese than interest in the biomedical aspects which prompts them to voice themselves with respect to weapons testing.

Dr. GLASS. Yes, I am sure there must be political motives involved in this.

Senator ANDERSON. We all recognize that the Russians may have done a little better propaganda job than we have. They have offered to stop tests over and over again. We do not like the circumstances under which they offered it. That may be one of the things which led the Japanese people to believe they will stop the tests. It is that the British and ourselves will not stop for all practical purposes, so we have gotten ourselves in a bad position internationally.

Representative COLE. I would like to have Dr. Glass indicate for the record the extent, if any, to which the genetic aspect is under constant survey by the United Nations Committee on the Radioactive Hazard.

Dr. GLASS. It is a very important part of that study. The United Nations Committee, of which Dr. Shields Warren is the Chairman, I believe, has met repeatedly over the course of the last 2 years to consider these problems. I am confident that our own Atomic Energy Commission has given it every degree of cooperation possible in supplying whatever data were requested.

Senator HICKENLOOPER. Mr. Chairman, may I ask Dr. Glass one more question?

Representative HOLIFIELD. The Chair would like to make a statement at this time.

I am sure every member of the committee thinks that this problem is so important that we are not going to curtail questioning of witnesses even though it disturbs our schedule. I hope the members will agree with me on that. This is a very important part of our hearings, and they should not be curtailed in any way as long as we have valuable testimony to be given or questions which the members wish to ask.

Senator HICKENLOOPER. Dr. Glass, this occurred to me a while ago when you were talking about desirable mutations. If a desirable mutation is had, do the desirable qualities of that mutation continue in the succeeding generations, or do they deteriorate?

Dr. GLASS. They would be just as permanent, we think, as the effects of a harmful mutation.

Senator HICKENLOOPER. So that once a desirable mutation is acquired, its characteristics would probably continue.

Dr. GLASS. Would be transmitted indefinitely; yes.

Chairman DURHAM. By radiation, you are speaking?

Dr. GLASS. Yes. There was a big "if" there, if I may answer your question, because I did earlier stress the fact that as a class of mutations produced by radiation are much more likely to be losses of the genetic material than are mutations that occur spontaneously. Consequently, I think the probability that a desirable mutation will occur as a result of radiation is even less than the probability that it might arise spontaneously.

Senator BRICKER. I do not think there is a member of this committee or anyone advised that does not realize that there is political propaganda being utilized by the Communists and the left wing groups generally in this field, and we may be giving some credence to it. On the other hand, it is an essential investigation that must be made. I think the public is entitled to all the information they can get.

Do you, as a scientist, or does your group of advisers, have any information as to what Russia is doing in this field of biological effects?

Dr. GLASS. We have very little information with regard to the state of genetics in Russia at the present time. I think Professor Muller would be better qualified to answer that question than I am. Perhaps I should postpone it.

Representative HOLIFIELD. We want to give Professor Muller plenty of time. When we get him on the stand we will ask him to testify on this point.

Thank you very much, Dr. Glass, for your very fine presentation this morning. I hope you will be able to stay for the roundtable conference, whenever we have it. I am afraid we will not be able to get at it at noon. We would like to put on this morning another notable, Dr. A. H. Sturtevant from the California Institute of Technology. Dr. Sturtevant, we are happy to have you with us this morning. You may proceed.

STATEMENT OF DR. A. H. STURTEVANT, PROFESSOR OF GENETICS, CALIFORNIA INSTITUTE OF TECHNOLOGY [8]

Dr. STURTEVANT. Mr. Chairman, the nature of the genetic effects and the quantitative estimates have been presented by Dr. Crow and Dr. Glass, so I shall not go over that ground. There is one point

[8] Date of birth: 1891. Education: Bachelor of arts, Columbia University, 1912; doctor of philosophy, 1914; honorary doctor of science, Princeton, Pennsylvania, Yale. Thomas Hunt Morgan professor of genetics, California Institute of Technology. Past president, American Society of Zoologists, Genetics Society of America, Pacific division, American Association for the the Advancement of Science. Kimber Medal for Genetics, National Academy of Sciences. Member, National Academy of Sciences Committee on the Genetic Effects of Atomic Radiation. Member, American Philosophical Society, National Academy of Sciences. (Submitted by witness.)

I should like to indicate, however, that sometimes has led to some confusion.

If there is an increase in the amount of radiation, within the range with which we are here concerned, there will be more mutations induced, but there will not be more serious mutations. Individually they will have the same range of effect as will those which were produced by the smaller amount of radiation.

Many geneticists have been disturbed by statements from the Atomic Energy Commission implying that there is no reason for any concern about possible damage to man arising from bomb tests. Recent statements by Commissioner Libby suggest that there is now an area of agreement on which discussion may be based. We are agreed that there is at least a possibility of damage to a small percentage of the population. We are, I think, also agreed that it is not now possible to present very exact estimates as to just how small that percentage is; and, further, that it is important to make studies that will improve the accuracy of such estimates.

Such efforts to improve the estimates must come largely from further research, both on the physical side (as to the nature and distribution of fallout), and from the biological side (as to the genetic and pathological effects of fallout). I should like here to express my opinion that, at least in the field of genetics—which is where I am competent to judge—the AEC has sponsored an excellent program, both in its own laboratories and in its grants to other laboratories. These projects seem to me to have been well chosen and well administered. In particular, there is, so far as I know, no pressure for the expression of conclusions or opinions that may be agreeable to the AEC.

I would like to add here that I should not like this statement read to mean that I feel that more money could not be used effectively. In other words, I am not in general in disagreement with Dr. Glass' plea for more support in this field.

However, there remain areas in which some geneticists are still disturbed by the AEC position. This, as has often been pointed out, arises in part from a difference in attitude concerning very small percentages. Various methods of calculating damage from fallout result in estimated numbers of affected individuals ranging from a few hundred to perhaps tens of thousands or even millions, depending in part on what assumptions one makes about the rate of future bomb testing. The highest of these numbers remains a very small proportion of the total population, and to some people this means that it is relatively unimportant. It is probably unimportant for the survival of the race, and it is relatively unimportant as an economic burden to society, though these could become serious matters if the rate of fallout should increase by a large amount. But hundreds or thousands or tens of thousands or more of individual human beings are involved, and to me it is not acceptable to say that they are unimportant, no matter how small a percentage of the total they make up.

Another point that some of us find disturbing is the insistence that the risk from fallout is much less than risks that we voluntarily

take repeatedly—such as those involved in riding in an automobile or going for a swim at the beach. While the risk is less from fallout, the essential point is that it is one over which the individual has no control. It has been argued that the risk from fallout is not very different from that of wearing a wristwatch with a radium painted dial. Even if this comparison is accurate, it still leaves out of account the fact that some of us do not wear such watches, and would complain loudly if anyone tried to insist that we and our children must do so.

There are biological risks from bomb testing. They are small—so small that no individual should be seriously concerned about the danger to himself or his immediate descendants. Nevertheless, when the entire population of the United States, or of the world, is exposed, it must be expected that there will be many individuals damaged, both in the exposed generation and in following ones.

I should like to lay special emphasis on the fact that every bomb test adds to the biological hazard. It follows that the most effective way to reduce future hazards would be not to test any more bombs. A geneticist cannot assume special competence in evaluating all the arguments for or against such a cessation, since the decision has to take into account many factors that lie outside his special field. But I should like to point out that biologists have made a serious effort to present an objective statement of the biological hazards, and it therefore seems to me reasonable to ask for as detailed and objective a statement of the reasons for continued testing as is consistent with security considerations. Some physicists have questioned the desirability of testing, on the ground that it gives almost as much information to other nations as it does to those making the test. Many nonscientists in this and other countries have argued that the tests worsen rather than improve, the international situation. These arguments, and those of the biologists, have never been publicly discussed seriously and in detail by those responsible for carrying out the tests.

Representative HOLIFIELD. Thank you very much, Dr. Sturtevant. Are there any questions?

Senator BRICKER. Of course, it would be impossible for us to do it unilaterally in light of what Russia is doing at the present time, and that may be the reason for your last conclusion.

Dr. STURTEVANT. That will have the same effect.

Senator BRICKER. That leads to your last conclusion that that is the reason there has not been serious discussion of cessation until we can get the international situation solved. Until that is done, there can be no effective steps taken by the United States alone.

Dr. STURTEVANT. I think the discussion should be as frank as possible in view of the security considerations involved. I was careful to add that.

Senator ANDERSON. Did you hear the statement that Dr. Langham made the other day when we were considering the possibility of limiting tests in some fashion where he suggested that we set a sort of ceiling of ten megatons of fission products as a reasonable limit of how much might be put in the atmosphere each year. Would you feel that something of that general nature is desirable until we are able to reach

some other step in this process. In other words, I think his thought was if we could limit to maybe 10 megatons the amount of fission products going into the atmosphere, there is a certain deterioration of strontium 90 and the decay of that material, and therefore we should not be putting more into the atmosphere than might decay out. Do you think it would be desirable to have some sort of limitation of that nature?

Dr. STURTEVANT. Speaking as a geneticist, anything which will decrease the amount is desirable. Speaking as a citizen, I realize that there are other considerations that have to be balanced against this.

Senator ANDERSON. His statement was based on some sort of international agreement. It was not to be done unilaterally by this country. He did feel it was desirable to make sure no more was going into the atmosphere than was falling out of the atmosphere each year. I think geneticists generally are in sympathy with that.

Dr. STURTEVANT. I would prefer to see less going in than was coming out, if possible.

Senator ANDERSON. I think he would, too.

Representative VAN ZANDT. Dr. Sturtevant, in the closing part of your statement, you say these arguments and those of the biologists have never been discussed in public seriously with those responsible for carrying out the tests. Would you recommend a public forum for this discussion, keeping it within the bounds of security?

Dr. STURTEVANT. That has been suggested recently as a possibility. I would rather see myself a statement by people who were responsible for it. In other words, by the AEC.

Representative VAN ZANDT. These hearings should constitute a forum where the biologists and those responsible for carrying out the tests can sit down and discuss the overall problem.

Dr. STURTEVANT. I think that would be very desirable.

Representative HOLIFIELD. Are there any further questions? If not, we will recess at this time until 2 o'clock.

(Thereupon at 12:35 p. m. a recess was taken until 2 p. m., the same day.)

AFTERNOON SESSION

Representative HOLIFIELD. The committee will be in order.

We are honored to have before us this afternoon Dr. Muller from the University of Indiana. It is my pleasure to announce to our audience today that Dr. Muller is a Nobel Prize winner.

As the Chair looks around and sees the group of children on our left here and realizes the importance of this testimony to them and future generations, it brings to my mind the gravity of the purpose of this committee, which is to bring out the scientific facts in this field.

Dr. Muller, you may proceed.

STATEMENT OF DR. HERMANN J. MULLER, PROFESSOR OF ZOOLOGY, UNIVERSITY OF INDIANA[4]

Dr. MULLER. Thank you, Mr. Chairman.

The subject of the genetic effects of radiation is, in my opinion, so closely bound up with that of the effects on the exposed individual himself that I feel it necessary, to begin with, to touch on that subject first.

I feel this is especially necessary because there has been a curious official silence concerning findings showing that the main damage to the exposed individuals themselves by small or moderate exposures to radioactive substances or X-rays consists of an insidious weakening of the body's resistance to the onset of infirmities and diseases of all kinds, expressing itself in a shortening of the length of life, and also consists in a long delayed production of certain specific disorders of which the most important are leukemia and some other malignant conditions.

Still less publicized has been the increasing evidence that the amount of these effects is simply proportionate to the total dose of radiation received, even when this has been given in tiny bits scattered over long periods. That is evidence for the conclusion that there is no threshold, some of which evidence you heard presented by Dr. Lewis.

I may say that I first heard of this principle of the shortening of life in amounts proportionate to the total dose received, no matter in how many small bits, in a very scholarly address given by Dr. Robert D. Boche at Oak Ridge in April 1948, and again at the Argonne Laboratories in November 1948. These were not classified meetings. The principle that he explained to them was based on work done by a number of different investigators during the war, working mainly at Rochester, N. Y., under the Manhattan project.

I mentioned these conclusions of Boche in a series of lectures given under the auspices of the Society for Sigma Xi, that were published 2 years later. But I was unable to refer to Dr. Boche's work except as addresses because I waited in vain to see publications along those lines.

Representative HOLIFIELD. Where were these addresses given?

Dr. MULLER. One was at Oak Ridge and the other at Argonne. They were open meetings. That is to say, it was not classified. They

[4] Date and place of birth: December 21, 1890, New York City, N. Y. Education: A. B., Columbia University, 1910; M. A. (1911), Ph. D. in zoology, physiology and biochemistry, (1916); D. Sc., Edinburgh University, 1940. Work history: Teaching fellow in physiology at Cornell Medical College, 1911–12; assistant in zoology at Columbia University, 1912–15; instructor in biology, Rice Institute 1915–18; instructor in zoology, Columbia University, 1918–20; associate professor (1920–25); professor of zoology, University of Texas, 1920–36; guest investigator (1937–38); lecturer in animal genetics, Institute of Animal Genetics, Edinburgh University, 1937–40; resident associate (1940–42); visiting professor of biology, Amherst College, 1940–45; professor, (1945–53); distinguished service professor of zoology, Indiana University, since 1945. Subsidiary appointments: Guggenheim Memorial Foundation fellow at Institut fur Hirnforschung, Berlin, 1932–33; senior geneticist, Institute of Genetics of Academy of Sciences of U. S. S. R., Leningrad and Moscow, 1933–37; civilian consultant to MED, 1943–44, to AEC, 1946–48; member of National Aiademy of Science, American Association of Advanced Science (fellow), American Society of Naturalists (vice president, 1932; president, 1943), American Philosophical Society, American Academy of Arts and Sciences, American Society of Zoologists, Genetics Society of America (president, 1947), American Genetics Association, Society for Study of Evolution, American Society of Human Genetics, Society of Experimental Biology and Medicine, American Humanist Association (president, 1956–57), Sigma Xi, Phi Beta Kappa, Alpha Epsilon Delta. Honors received: Annual $1,000 award of American Association of Advanced Scientists, 1937; Nobel Prize in physiology and medicine, 1946, for the production of mutations by radiation; presidency of Eighth International Congress of Genetics, Stockholm, 1948; honorary D. Sc. from Columbia University, 1949; Kimber award in genetics of National Academy of Sciences, 1955; Virchow medal of Rudolph Virchow Medical Society of New York, 1956. (Submitted by witness.)

were not published and they were not open to the press so far as I know, so I only knew about the matter verbally.

Representative HOLIFIELD. Were they in the form of prepared addresses?

Dr. MULLER. Prepared addresses, and with charts of data; yes.

Representative HOLIFIELD. Who did you expect to print those?

Dr. MULLER. I expected he would have an article on the subject. Later I found that there was a classified article of his in 1946 on the subject. It was later declassified, but I am not sure when. It did not get out into the general literature. It was not spoken about to any extent. In fact, although I do not know whether it had any relation to that silence or not, there was an attempt made to prevent the publication of that part of my own lecture which contained this material. No special reason was given. I do not want to go into the details of that because it may have been accidental, but it is a very curious incident.

Representative HOLIFIELD. You said there was an attempt made?

Dr. MULLER. The editor had agreed to publish the whole article. It was presented in 2 parts because it was too long to go in as 1 article. Both parts were to have been published. After the one part had been published I was told that they did not want to publish the other part, that that was enough. The first part concerned itself with the effects on future generations and the second part with the effects on the exposed generation itself.

Representative COLE. Mr. Chairman, would Dr. Muller give the time when this incident occurred?

Dr. MULLER. The lectures were given in 1948. They were published first in 1950. So that occurred in 1950.

Representative VAN ZANDT. Dr. Muller, did the thinking at that time fit in with the problem of today?

Dr. MULLER. Yes. It was not as acute because we did not have hydrogen bombs yet.

Representative VAN ZANDT. Were there any predictions in those papers?

Dr. MULLER. I called attention to these points; yes. We did not know much about fallout yet.

Representative HOLIFIELD. Dr. Muller, what type of a meeting was this? Who set the meeting up, and where was it?

Dr. MULLER. One of them at Oak Ridge was set up by the Director of Research, Dr. Hollaender, a very eminent biologist and geneticist. The other was called under the auspices of the Argonne Laboratory on the problem of the effects of low doses of radiation.

There were many interesting papers there. For example, one which showed the lessening of the number of white blood cells in workers at Los Alamos who had received only 25 r. of radiation over the whole year. Nevertheless, by taking accurate statistics of the whole group it was possible to show the effect. One would not have been able to see it in one individual because it fluctuates too much.

Representative COLE. Mr. Chairman, I am curious to know, Dr. Muller, is it your feeling that there was a deliberate attempt on the part of the responsible officials of the Government, whether of the Atomic Energy Commission or the Manhattan Engineering District, to suppress the expression of your views on this subject?

Dr. MULLER. I would not like to express an opinion about that. It may have been a coincidence. But I was very surprised that no one else said anything about the matter in any semipopular or popular publication. This was a semipopular publication.

Representative VAN ZANDT. Dr. Muller, do you feel that had the papers been made public at that time that it would have eased this acute problem we are faced with today?

Dr. MULLER. Yes. I think that any such knowledge is to the good because the public should be prepared to know the facts and if they find out later that something has been withheld from them—I will touch on that later—they are apt to exaggerate the importance of the facts. I think that there was a feeling probably amongst many people who felt that these facts needed further verification, that it was unwise to let the public know about them until they were proved up to the hilt.

To me it seemed that the main principles were already far enough established to warrant a public airing, since if true, they were of such grave concern.

Senator ANDERSON. Doctor, this morning there was some reference made to Russia, and it was suggested that one of the witnesses testify about the situation in Russia. Here we have the situation in this country today where the foremost geneticists of the country are testifying before an open hearing. Is that the situation in Russia, or are geneticists in somewhat different circumstances over there?

Dr. MULLER. There are few geneticists left. I would rather postpone questions on Russia until we get through this because we might go on indefinitely. I think we can draw lessons from Russia.

Senator ANDERSON. I knew you had worked in Russia.

Dr. MULLER. Yes.

Senator ANDERSON. And therefore have some opinions. I hope you give them when you finish this afternoon.

Dr. MULLER. I would be happy to answer to the best of my ability any such questions as you might have.

These facts, which I think Dr. Hardin Jones and Dr. Russell will take up in their talks, about the shortening of the length of life seems to me to be extremely important. I think it can be shown that they and the long delayed malignancies such as leukemia constitute by far the greatest damage of all the effects of radiation on the exposed individual himself. That is, of moderate and small doses. I am not speaking of the radiation sickness and death that occurs from very high exposures such as direct atomic bombing.

Therefore, I thought it was very curious that these effects were not discussed more and were not in fact investigated more. It seemed to me if there was an uncertainty then it should have been pushed to find out is it true or not.

We did finally in 1954 have papers on this work published in declassified form in a highly technical volume edited by Dr. Blair almost 10 years later. Since then the effects have been talked about to some extent. They were mentioned in the Pathology Committee report of the National Academy of Sciencies. So far as I can remember in the National Committee on Radiation Protection—I happened to belong to its Subcommittee on External Dose for some years—there was very little mention of them. I doubt very much that they were gen-

erally realized by workers in the field of radiology, for example, or by biologists in general.

In respect to the fact that probably there is no threshold, that these effects are proportional to the dose, in this respect these effects of radiation—and also the leukemia—on the exposed individual himself resemble those produced by the radiation in weakening descendants.

You have heard Dr. Glass and Dr. Crow say that geneticists are convinced that there is no threshold for the genetic effects and that others, too, now accept that principle for the genetic effects.

If this is true of these other effects, and it is certainly time we knew whether it was—I think the evidence is convincing that it is—then this important resemblance between the effects on later generations and on the exposed generation is probably not an accidental resemblance. For there is growing reason to infer that this shortening of life and the other long delayed damage done to an exposed individual have their basis in damage done to the genetic material—the chromosomes and their contained genes—of the body's ordinary cells, those of the blood, skin, glands, and so forth, similar to the damage done in his reproductive cells that is passed on to later generations.

In the body's own cells, however, we have good reason to infer that more of the damage that becomes expressed is done by breaks of chromosomes and in the reproductive cells by mutations of genes.

Let me use the blackboard a moment.

Here is a cell, and there is its nucleus, and in it there are these long threadlike bodies which can become condensed into sausage-shaped forms, called chromosomes, that consist essentially of strings of minute particles called genes, each of which, as Dr. Glass explained to you, has some specific effect in furthering the functioning of the body.

Radiation has two main kinds of effects on this genetic material. Let me again say that every cell of the trillions of cells in the body has this genetic material the same as the reproductive cells, and radiation can affect the genetic material in the body cells the same as in the reproductive cells.

There are two main kinds of effects on the genetic material. One is a break in a chromosome. Two, a change in the inner composition or arrangement of parts of the gene itself.

The breaks in the chromosomes have more effect on the exposed individual himself when they happen in the somatic cells for this reason. If this cell in the diagram is one that is going to later reproduce itself in the body to form more cells, or to multiply, as our skin cells must—as skin is always sloughing off and has to be replenished by multiplication of the cells in the lower part of the skin, and it is the same with many other parts of the body—then these chromosomes have to reproduce themselves, as Dr. Glass explained, forming duplicates of themselves. Then they are drawn apart by the process of cell division or mitosis, forming 2 groups of chromosomes in the 2 daughter cells. But if the chromosome is broken, it may kill the whole cell at the time or shortly after division by this mechanism, or it may result in very abnormal cells.

There is a point on each chromosome, which becomes attached to a fiber that pulls the 1 daughter chromosome to 1 pole and the other to the other pole, so that when you get the cell dividing into 2 daughter cells, one daughter cell gets one representative and the other gets the other representative of that duplication process, and they thereby come

to have like material. The chromosome gets pulled at that particular point. But the part beyond the break won't be pulled in because it has nothing to be pulled by. It gets left behind, and the cell is left without all those genes.

Moreover, where the chromosomes have broken, there is a sort of stickiness which causes them to join together at their raw ends if they happen to touch, which is very often the case, and then, when they get pulled apart, they form what we call a bridge between the two cells. They can't, in that case, get apart. That chromosome bridge, then, connects the two cells, which often die in consequence. Therefore, as a result of the chromosome break, we often have a cell death.

Dr. Puck, of Denver, studying human cells in tissue cultures, has found that, with doses of radiation given at a high dose rate, it takes only about 90 r. to cause the death of about 50 percent of the cells. In other words, that happens to about 50 percent of the cells in the tissue culture. It will only happen to cells which attempt to undergo division.

Your brain cells, your kidney cells, as Dr. Warren said yesterday, are not affected much by radiation. On this interpretation the reason is easy to see, because they have stopped dividing for life. You have the same cells of these kinds for life, whereas your skin cells, the cells of the intestine, et cetera, have to keep replenishing themselves by division. It is only when they come to replenish themselves by division that these tangles take place that result from the breaks in the chromosomes.

On that basis it is easy to understand the rule that Dr. Warren referred to yesterday, sometimes known as the law of Bergonié and Tribondeau, established about 1906, that it is the tissues with rapidly dividing cells that are the most damaged by radiation. The damage does not take place in the cell until division occurs. When that happens in a germ cell, those cells generally die and seldom take part in the production of offspring. That is why this is not important for the later generations. But it is important for the generation itself. It takes place both in the germ cells and body cells, but it is in the body cells that the main damage of this kind is done.

I will give you an illustration of that. In the people that were bombed a long time ago at Hiroshima you can see a lot of little opaque points in many of them in the lens of the eye where evidently cells have been badly damaged. That damage did not appear until much later when the cell probably undertook to divide. The reason you can see it there is because the lens is a transparent tissue. I think there is reason to believe that this happens in all the tissues of the body that contain cells that are subject to division. These tissues would, therefore, be weakened.

It is true that other undamaged cells would tend to replenish the damaged places. But that replenishment or regeneration, it is to be expected, will not be complete and perfect. Therefore, there is a certain amount of damage left. That damage, you can see, would be a generalized damage all over the body, wherever there are these dividing tissues. Therefore, it would be expressed as a weakening of resistance to disease and infirmities of all kinds, somewhat like what occurs in aging, since then, also, our resistance to bodily ills decreases as the functioning of the cells or tissues weakens.

I do not say by any means that is the proved explanation, though we do know this phenomenon of chromosome breakage occurs, and, to me, having examined the evidence, it seems by far the most reasonable explanation. That is, the bodily damage in general is to be explained in this manner rather than by some damage to the other materials of the cells.

There is a good deal of other evidence showing that it is this damage to the genetic material, to chromosomes and genes, that is by far the most important damage, and that you have to have the radiation strike at or in the close neighborhood of the chromosome or gene before you can damage it. For example, experiments done in Chicago by Zirkle and Bloom show that when they were able to direct a minute beam of radiation (protons) through the cell, it was only when they actually hit the chromosome or right close to it that you then got chromosomal damage. If you hit right there, when the cell divided you had the bridges form.

Other experiments similarly show that if you only hit the rest of the protoplasm you do relatively minor damage compared to what happens when you hit the chromosomes or genes.

You can readily see, I think, that since we know through experiments in geentics that the frequency of these breaks, like the frequency of the mutations of the genes, is linearly proportional to the dose of radiation used, no matter in how small bits it is divided, then you might expect a derived effect, such as the decreased resistance to disease and consequent shortening of the life span also to be linearly proportional.

It is true that at high dose rates of radiation you sometimes have two chromosomal breaks near together and then you can get entanglements which would not happen if you have low dose rates. At low dose rates you therefore expect the effect to be proportional but at the high dose rates to go up even more steeply.

I think it is also very probable that even the very pronounced effects of heavy exposure, such as you find in radiation sickness, such as the nausea, the drastic lowering of the count of white blood cells, the bleeding internally, are also due to this genetic damage to the somatic cells.

For example, in a very careful investigation, Dr. Quastler showed that the intestinal injury that leads to death after high doses is caused by the failure on the part of the cells of the intestine that normally replenish the rest every 3 or 4 days to carry out this task. Owing to being so badly damaged, they fail to survive the process of cell division in normal condition.

These effects of heavy doses do have thresholds, not because there is a threshold in the production of chromosome breaks, but only because you do not see clinical symptoms unless you have damaged a certain number of cells.

If this point of view is correct, then I think it is to be expected that even the damage to the exposed individual could be better investigated by people who have the genetic point of view about it. They would be the ones who would be more likely to look for an effect that has no threshold. I think it is not at all surprising, therefore, in view of the probable mechanism of these effects, that it has taken geneticists, notably Boche, in the case of life span, and Lewis, in the case of the

effect of leukemia—both, by the way, *Drosophila* geneticists originally—to uncover the evidence for the cumulative nature of the damage to exposed individuals. Moreover, I think the research should be continued along those lines.

Doctor Friedell said yesterday that the important thing to know is the mechanism involved. I do not say we know it. But I think we have more than a pretty good hunch. And we have to follow these hunches, even if they lead to conclusions that are distasteful to some people, such as that there is no threshold. But if we calculate (as Dr. Hardin Jones will calculate with you) the amount of effect of a given dose on the length of life, we find that the dose which is now the maximum permissible dose for occupationally exposed workers, namely, 50 r per 10 years, would lead in 40 years of their work to 200 r. and would thereby deprive them—we may want to change this estimate; we can't now say exactly—of some 4 years of their life. Perhaps 1 year of their life lost for each 4 years they work, or something like that.

My main point here is that if there is no threshold, then the loss is of a sizable amount and we had better pretty soon find out how much. We meanwhile have to act on the supposition that it exists. Nevertheless, this effect on the length of life of the exposed generation is not as great as the effect in damaging future generations.

Representative HOLIFIELD. Why is that, Doctor? Will you explain that?

Dr. MULLER. Yes. Let me now speak of the damage to future generations. I said that not much of it was caused by the chromosome breaks but most of it by the mutations of the genes. The reason the mutations of the genes do not cause much damage usually to the exposed individual is because most of them are what we call recessive. There is a normal gene from the other parent that has a dominating effect, although it may very well be the case that in leukemia we have a dominant gene. But mutant genes that are decidedly dominant are not the usual ones.

As for later generations, the chromosome breakage cases are largely weeded out by the cells dying before they get to the next generation. The mutations of the genes, however, persist and are handed down as mutant genes. These mutant genes also are usually recessive, as Dr. Glass explained. The person usually gets a normal gene from the other parent and that has the dominating effect. But the dominance is not quite complete usually, and that slight deviation from completeness is very important.

Suppose it only reduces by 5 percent the chance of an individual surviving to maturity; that is a chance of death of 1 in 20. It does so by handicapping him in some way. It is usually a slight handicap that he hardly realizes is there. He takes it in his stride because he has had it perhaps from birth, though it may not have expressed itself always, and it is mixed in with his other infirmities. All of us have some. No one is perfect because there is no such thing. But by it his biological survivability is reduced by just that much, and he hands that weakness on down to the next generation, and after awhile it will take its toll by happening to come in a combination of circumstances where it will kill or prevent reproduction. So the thing will finally die out.

As Dr. Crow explained, if it gives a chance of 1 in 20 of causing death in 1 individual, it tends to pass down to 20 individuals before it takes its toll. So it hampers correspondingly more persons than a gene that killed outright. Therefore, as Dr. Crow explained, the slight mutation is as bad in the end as the mutation with the big effect. Moreover, we are all of us full of these defects that come from the past. A hundred things, each of which does a one-hundredth of as much harm, are together as bad as one thing that does that much harm.

Representative HOLIFIELD. Before you leave that, is it not true that if a general population receives a dose of radiation, as would occur in the general raising of the rate in the atmosphere, that there would be a greater chance for the mating of recessive genes?

Dr. MULLER. If both people had been exposed, no, the increase in the chance would be insignificant, contrary to a common misconception. Because the chance is so slight that it should have been the same gene that was effected in both parents. There are more than 10,000 genes, we believe, and if each parent had an affected gene, therefore, the chance would be only 1 in 10,000. So that is virtually ruled out.

Senator ANDERSON. May I go back one step? Did I understand you to say that if, for example, the exposure was 50 r. every 10 years, and a man worked for 40 years, making a total of 200 r., his life might be shortened as much as 1 year for every 4 years of work?

Dr. MULLER. No; I am sorry. I made a mistake. I means 1 for every 10. Dr. Hardin Jones will give you the latest information.

Senator ANDERSON. You said 1 for every 4.

Dr. MULLER. Yes. I was thinking of 4 times 10, and I got the 4 instead of 10.

Senator ANDERSON. So that would be 4 years shortening.

Dr. MULLER. Yes. That would be the provisional estimate I made a long time ago and we may have better data now. I think this is probably a conservative estimate.

Dr. JONES. A very reasonable estimate.

Senator ANDERSON. Thank you.

Dr. MULLER. These effects then, being slight, are usually not recognized as such. Certainly you could not tell which mutation was caused by radiation, if radiation had been received by the parent, and which was not. The induced mutations are like those already existing in the population but are added to them. The only way you can tell they have been produced is by means of a very exact statistical study on large groups, comparing those that have been irradiated and those that have not.

Through work on the fruitflies where we have the most exact knowledge to date, unless Dr. Russell has more exact knowledge on mice now, we can get a kind of minimum estimate of the amount of damage to the children by a given amount of irradition of the parents. Although there would not be time to show you here the way the calculations are done—and they do have a considerable error—I think it is possible to show that the amount of damage to the offspring of parents that had received a certain amount of radiation to their whole body, in the case of fruitflies, would be something like the amount of damage in the parents themselves.

A comparison, however, would show that, when, X-rays or gamma rays were used on fruitflies, the damage to the offspring would be somewhat less than to the parents. You may think that is contradicted

by what I said before when I said the damage to future generations is greater than to the parents. There is no real contradiction because we are here referring only to the first generation of offspring. But they hand the damage down to their offspring, and so on.

As Dr. Crow explained to you, the damage does not die out to half its value for probably scores of generations. So you have to multiply this damage to the first generation of offspring by scores, maybe by 50, to find out what the total damage to future generations is of just the 1 exposure to 1 generation. When you have done that you have obtained a figure of damage to future generations that is far greater than what is done to the exposed generation itself.

I think most people would not be impressed with the weaknesses caused in future generations, even though future generations would feel them. Therefore, it is my contention that it is a very good thing that people's own life span is shortened; that is, that there is a demonstrable effect on the generation itself that is exposed, because they will take notice of this effect on themselves, if they are allowed to know it. They will then take precautions that will save future generations from a lot more damage than it saves themselves.

The prolonged official reluctance, at least until a year or two ago, to give information in popular form regarding these major types of radiation damage, that in the exposed individual himself expressed in the shortening of life and long delayed malignancies and that expressed in the descendants, and the reluctance to give information regarding the conclusion of some of those who have worked most directly in the field that even the tiniest doses add up accurately to determine the amount of these effects without any threshold, has, I think, undermined the confidence of large numbers of well-intentioned people in the judgment and the intentions of the responsible governmental authorities, because the facts have, after all, leaked out or have been suspected by the public, and they wonder why nothing has been said about it.

As I said before the National Academy of Sciences 2 years ago:

> So many of the public are already aware of the genetic damage produced by radiation that their morale is weakened and their apprehensions are increased when they see that the damage is denied by prominent sponsors of our national defense. Thus the door is opened for their acceptance of the defeatist propaganda which alleges that even the tests are seriously undermining the biological integrity of mankind. In this situation the only defensible or effective course for our democratic society is to recognize the truth, to admit the damage, and to base our case for continuance of the tests on a weighing of the alternative consequences.

Now when we do this, we conclude that the number of lives that will be seriously curtailed or injured throughout the world in future generations, as a result of the tests already held—supposing that they continue at this rate for perhaps 10 years longer—is in all probability in the hundreds of thousands or millions, and is therefore enormous. We should recognize that.

Despite all the uncertainties in regard to the exact figures, I think it was not possible to make clear to you how much careful work these estimates were based on, and the fact that although there may be an error of what we call a factor of 2 or 3, that is, that the true figures may be 3 times as much or only a third as much, nevertheless it is very unlikely that they should be less than, I would say, a third as much. In other words, the values given to you by Dr. Crow are those which are most likely in the light of present knowledge.

So I think we must recognize that the number of lives that would be seriously curtailed or injured will be in the hundreds of thousands or millions, and is therefore, enormous.

Senator ANDERSON. Doctor, you say that a number of lives seriously curtailed or injured from tests already held?

Dr. MULLER. Yes. I should modify that. I should say from tests held at the rate at which they have been held.

Senator ANDERSON. As they are now going?

Dr. MULLER. Yes.

Senator ANDERSON. That does make some difference.

Dr. MULLER. Yes.

Senator ANDERSON. That would damage, you think, hundreds of thousands or perhaps millions, and you say that is within a probability factor of 3?

Dr. MULLER. Yes.

Senator ANDERSON. A third as much or three times as much?

Dr. MULLER. I would put it at that.

Senator ANDERSON. Then it would be a very substantial number of lives if it is on the smaller side and an enormous number of lives on the larger side.

Dr. MULLER. Yes.

Senator ANDERSON. Doctor, do you believe that a number of geneticists agree with you in that point of view?

Dr. MULLER. I do, yes. They might differ as to where to put the factor. Some might say 2. Some might say 5 or 6.

Senator ANDERSON. This would sort of imply that there is no threshold.

Dr. MULLER. Yes.

Senator ANDERSON. That it starts immediately.

Dr. MULLER. Yes. That is because of the mechanism that Dr. Pollard explained. The thing strikes or it doesn't strike. If it strikes it does the damage even if there was only that one strike. He made the comparison with a lightning strike occurring in a large space and a long time. in which however that strike would be just as effective.

Senator ANDERSON. I ask that question because of the discussion we had this morning of having some group to come in and discuss these figures with a responsible group such as the Commission itself. You do feel that the geneticists could make a strong case in support of that?

Dr. MULLER. Yes, especially those who have worked in the field.

Senator HICKENLOOPER. Dr. Muller, in your prepared statement I notice you said with respect to that, and I quote from the prepared statement as follows:

> As I stated before the National Academy of Sciences 2 years ago, it has caused—

that is, certain conceptions or misconceptions—

> people to lend too ready an ear to the alarmists who declare that the genetic material of the human race is seriously endangered by the fallout from the test explosions themselves.

I do not know whether you got to that or whether you intended to do it or not.

Dr. MULLER. No. I read a more detailed statement on the subject, taken from the discussion that I gave before the National Academy

of Sciences. I read a part of that discussion. But I also stand by the statement as I have it in the text that you have just read.

Senator HICKENLOOPER. With respect to these numbers which you refer to as hundreds of thousands or millions, do I understand the connotation of that to be that that in fact is extremely minute as compared to all the human beings for ensuing years?

Dr. MULLER. Yes.

Senator HICKENLOOPER. Although it is large in numerical value standing by itself.

Dr. MULLER. That comes in the next sentence, you will see, where it says:

Nevertheless these injuries, being scattered over the whole earth and through hundreds of years—

I should have said thousands—

are relatively very few, in comparison with those due to other causes, including natural mutations. Moreover, the suffering to be entailed, although enormous in absolute terms, must be very small relatively to that which might follow from any serious mistake in the conduct of international relations.

Senator HICKENLOOPER. Therefore, Doctor, it becomes a matter of relative value in this particular field.

Dr. MULLER. Yes.

Senator HICKENLOOPER. Some things we may have to do, such as getting into war where we do not want to kill people, whether by bullet or disease or anything else, but we have to balance security and necessity against the hazard and strike a balance as to our conduct.

Dr. MULLER. Yes. I do not mean that when we strike that balance—I am not trying here to say which way the balance will be struck.

Senator HICKENLOOPER. I understand. You are making the point that someone must exercise judgment and determination in the light of all the circumstances.

Dr. MULLER. Yes. I would agree with Doctor Sturtevant that one life is a serious matter.

Senator HICKENLOOPER. Yes, without doubt.

Representative HOLIFIELD. You are really making a plea that all the facts be known before the decisions on policy are made.

Dr. MULLER. Yes.

Representative HOLIFIELD. And no facts be repressed.

Dr. MULLER. Yes.

On the other hand, the consequences of a full-fledged war, with its heavy irradiation of large numbers of people on both sides, would be inordinately more serious in its effects on the human genetic heritage as well as in its more direct effects. It is this consideration which, in my opinion, makes a continuation of test explosions a monstrous mistake of policy for both sides. Of course it would be absurd to expect one side to stop without the other. But a continuance by both sides would tend to lead the world nearer to a war that even with present techniques would result in the cataclysmic ruination of humanity in general.

May I add that the means of destruction are now so advanced on both sides that further advances by one side alone could not save it in the case of a war from becoming itself destroyed. By war I mean an atomic war, because I do not think you can have a world war any-

more without a thermonuclear or atomic war. I do not think it is realistic to suppose that you can.

Senator HICKENLOOPER. This illustration, I realize, is not exactly on all fours with the situation we have here today, but we are concerned with the danger and propriety of continued tests in the world.

Dr. MULLER. Yes.

Senator HICKENLOOPER. I presume all of us would earnestly hope that we never had to test atomic weapons. That perhaps would be the ideal. There are certain political factors that enter into those decisions, but by the same token I presume that we want to save thousands of lives in this country every year and we could just abolish the manufacture of automobiles and go back to riding horses. It seems to have struck a balance in the minds of people that transportation is important and we keep making automobiles, people keep getting killed by the thousands on the highways every year. We are all sad about that.

The point I was attempting to understand in my own mind is that there is a balance which someone must determine as to the ultimate good to either us or the world in this atomic field and whether or not we continue.

Dr. MULLER. I would accept that, except that I would rather say, "which every one has to help determine."

Senator HICKENLOOPER. Yes, indeed.

Dr. MULLER. I might add in this connection that in my talk to the National Academy 2 years ago I stated it to be my belief at that time that a continuation of the nuclear tests was necessary. I still think that this was the case at that time but I think the situation has changed since then. But there I am not speaking as a geneticist.

Senator HICKENLOOPER. I do not know whether I understand or not, but may I ask you, are you advocating that the United States stop testing weapons unless we get reliable agreement that other nations in the world would stop also?

Dr. MULLER. Of course not; no. The more that we can get people of the world to recognize the terrific damage that nuclear war will bring to them all, I think the more they will see the light on that point.

Senator BRICKER. Are you going to discuss later, Doctor, the answer to the question I asked this morning in regard to the experimentation that is going on in Russia?

Dr. MULLER. Yes. Just a little more here—I am on the last page on a somewhat different topic, but it is all related.

In order that the grave biological effects of radiation may receive due recognition and study—and I have tried to show you that they have not received due recognition and study—and may duly influence our policies and procedures, it is important that persons with a systematic background in genetics be placed in positions in which the decisions involving these matters are made. Truly this should be the case if there is any chance that genetic processes lie behind all the major damage done by radiation to man. Yet this is not the case at present.

For example—and let me not be misunderstood here—I have the highest regard for Dr. Shields Warren and for Dr. Brues and their associates, but I think it is important in this connection to point out that the official delegates of our country on the United Nations Scien-

tific Committee on the Effects of Atomic Radiation—and those are the gentlemen I have just mentioned—are neither of them geneticists. I am sure neither of them would wish to claim to be. I mean by that they would disclaim it.

Representative COLE. On that point, Doctor, do you know whether other members or official delegates from other countries on this committee are geneticists?

Dr. MULLER. There is one geneticist of bacteria, Dr. Appleyard of Canada. There is Dr. Caspersson from Sweden who studies chromosomes and other cell materials through the microscope. He is not exactly a geneticist. There is an alternate, Dr. Gopal Ayengar, from India who is a geneticist. Dr. Bacq of Belgium is in fields related to genetics.

So far as I know, those are the only ones that come near the subject of genetics who are on that committee. I stand to be corrected. They can, of course, and have, at least at the last meeting, I understand, had some geneticists present as consultants. Yet the chief discussions of that committee to date, so I have been told, have been on directly genetic matters, on these very questions here, especially on the effects on future generations.

You may remember that this country insisted that the delegates be chosen not by sciences but by countries and that the delegates by countries be chosen by the government and not by the scientific bodies. Some other countries put up strong resistance against that, but finally accepted it.

It may be noticed that most of the nongeneticists who deal with these matters, as I think is clear from the discussions of yesterday, are on the same side. They are on the other side from geneticists in regard to the major question of whether there is a threshold or whether the major effects on the body are linearly proportional to the dose all the way down to zero. That is an important issue in assessing the effects not only of the tests, but also of the peacetime uses of atomic energy.

I might say that when it comes to another body that is very important in this connection, the National Committee on Radiation Protection, we are in a better situation. Dr. Glass here, a very good geneticist, if I may say so, is a member of that committee, who was newly appointed just a few days ago. I was a member of one of the subcommittees for some years, although I am not sure whether I still am or not.

Representative COLE. Mr. Chairman, may I clarify the record? I understand Dr. Glass had been a member of this committee for 3 years.

Dr. MULLER. No, that is another committee. That is the Atomic Energy Advisory Committee on Biology and Medicine. I am now speaking of the National Committee on Radiation Protection which is under the auspices of the National Bureau of Standards and which is the one promulgating the permissible dose which we had explained to us the other day on the blackboard.

The latter committee do have, as I have said, a geneticist here and there. However, they have official representation from about 15 different organizations, mostly of a medical or governmental nature. Yet they do not have one official representative from any of the professional genetic organizations, such as the Genetics Society of America,

the American Society of Human Genetics, the American Genetic Association, or the Society for the Study of Evolution, all of which are in my opinion as closely concerned with this matter as for example the Radiological Society. Consequently, there is not sufficient representation among them of that genetic point of view of the mechanism which leads us to expect no threshold and to take the matter more seriously at small doses. This circumstance, I think, provides the reason why the record of this committee's decisions on the permissible dose, which as Dr. Taylor presented the matter yesterday appeared to show that they were so cautious, in actuality showed that the first dose they set was far too high, so that they had to set it lower. Then they found the second limit also was far too high and again they came down. And recently they found that the third limit in turn was too high and they came down once more. This does not indicate that they have been so cautious. It means they have not been cautious enough. The geneticists would not have set so high a permissible dose in the first place, on the basis of what we knew 30 years ago.

The grounds for the reduction in permissible dose that was made by the committee a few years ago, prior to the issuance of the National Academy's report, did not lie in considerations of genetic damage. For the permissible dose handbook specifically stated that this dose (of 0.3 roentgens per week) was set without regard to genetic effects. The geneticist members objected to that but it was carried anyway. In other words, it was known that the dose was considered too high on genetic grounds but it was adopted in spite of this, although it was acknowledged that it might be reduced again later.

Now that the Academy has made its report it has in fact been reduced a great deal more. I agree however with Dr. Glass, that it is probably due for even further reduction.

A similar attitude is reflected in the omission of any mention of the genetic effects of radiation in the courses on radiation in relation to health that are given both for our own people and for foreign selectees under AEC auspices at Oak Ridge. It is not enough to have biologists of some sort, or medical men, to reach decisions on these matters, unless they include a strong contingent of geneticists and of those who have a genetic point of view. Others are not likely to admit the danger from small doses.

In view of this situation and of the notorious resistance to the acceptance of genetic principles on the part of so many, not only of governmental appointees in the policymaking positions, but also of so many of the medical profession, a resistance that has prevented the medical profession for 30 years from duly protecting themselves, their technicians, and their patients when X-rays are used medically, and that has thereby subjected the reproductive cells of our population to very much more radiation than that from fallout—it is my opinion highly important that a National Radiation Health Institute be established as a part of the United States National Institutes of Health, but only if it contains a solid core of competent and versatile geneticists as one of its major features.

It is true that there is excellent research on the genetic and other effects of radiation being carried out in our country and that a considerable amount of it is made possible by the support or is done under the auspices of the AEC. This research, however, does not sufficiently insure the all-around consideration and study of these matters in rela-

tion to public health and well-being, and the promotion of adequate measures in application of the conclusions reached.

If anyone wishes to ask some specific questions on the Russian aspect of the situation, I would be glad to take them up.

Senator BRICKER. I just wanted him to discuss the situation and whether they are conscious of the conclusions you have come to and are presenting to us and what research is being done there with regard to the effects of fallout.

Dr. MULLER. I have to infer from my knowledge of Russia derived from various sources, including firsthand information gained 20 years ago, that they are and will be having to follow our lead. We can't look to them for useful information at present along these lines. For, as I think most people realize, there was a purge of geneticists and an expurgation of the subject of genetics from teaching in the school and universities, from the boards of publication of journals, and from research institutes. It has not been taught to students for about 20 years. Most of the leading geneticists were somehow done to death, and I say this advisedly.

Chairman DURHAM. You say they will have to follow us. Do you think they would follow us?

Dr. MULLER. Yes.

Chairman DURHAM. Do you think so?

Dr. MULLER. Yes. There are a few geneticists left, of course. I think that some of the politicians in leading positions, since Stalin died, realize the folly of their old ways in regard to the subject of genetics. We have solid evidence that it is now possible to advocate the principles of genetics and to do some research in it.

A few of the old research workers are left, and there are said to be plans to give them positions in which they can resume their genetic investigations. However, the quacks have not by any means been disestablished yet, although they do not hold as commanding positions as they had before. One of the older geneticists, Dubinin (he was not old 20 years ago), was even rumored to have been selected as one of their delegates on the U. N. Scientific Committee on the Effects of Atomic Radiation. If so, Russia did better than most of the other countries in regard to that committee because Dubinin was a real "honest-to-goodness" geneticist.

Chairman DURHAM. You do think that Government officials are getting advice on genetics?

Dr. MULLER. They are beginning to get advice on genetics again. But I also note that the quack group are still strong. We have proof of that in publications and in the fact that in the Conference on Genetics that was held in Japan last September the Russians sent, I believe, four delegates, and all of them belonged to this quack school. So there is a division on the matter in Russia now.

Chairman DURHAM. What do you think is the reason for the Russians not permitting the genetic scientists to take part in the United Nations?

Dr. MULLER. The Russian, Dubinin, is a geneticist. Most of the other countries didn't seem to realize that geneticists were needed, for this committee seemed to assume that physicians would know about the subject. However, you will find very few physicians in this country that have an education amounting to anything in genetics.

Chairman DURHAM. Did I misunderstand you? I thought you said they would not permit him to go to the United Nations panel.

Dr. MULLER. No. I said I had heard, but I cannot verify, that Dubinin was to go to that meeting as an official Russian delegate. Whether he went or not I do not know. Perhaps someone here knows. I would be interested to know if he did.

Representative HOLIFIELD. Dr. Muller, you have spoken in two instances in your presentation here of the prolonged official reluctance and the curious official silence. Is it not true that you were invited to give a paper at the Geneva Conference a couple of years ago?

Dr. MULLER. Yes.

Representative HOLIFIELD. The Geneva Conference on Atomic Energy?

Dr. MULLER. Yes.

Representative HOLIFIELD. Did you give it?

Dr. MULLER. It was printed in the proceedings.

Representative HOLIFIELD. That is not quite an answer to my question.

Dr. MULLER. No, I did not give it there. I was prevented from giving it.

Representative HOLIFIELD. Who prevented you from giving it?

Dr. MULLER. The story has some complications of detail, but the essential thing is that it was called off by higher echelons of the AEC. That was actually shortly after this article of mine had appeared in Science that I quoted from earlier, in which I said there had not been enough airing of the matter.

Representative HOLIFIELD. Were you given any reasons as to why you were not allowed to give your paper?

Dr. MULLER. Yes; there was not room for me. Also they were sorry they had to notify me so late because they had only just received word so late from the International Committee. It was afterward found that it was not the International Conmmittee that had asked to have my paper excluded. They had approved of having it given. That expression was used, however, in the official letter written to me by the AEC authority.

Representative HOLIFIELD. Are there any further questions?

Representative COLE. Mr. Chairman, it had been my understanding that the committee was going to allow our staff specialists in this field to interrogate the witness in any area in which they felt there was some need for further amplification. I would like to inquire if Mr. Hollister might not have some questions of Dr. Muller. I would suggest that hereafter Mr. Hollister would be invited to interrogate. He is reluctant to inject himself into the interrogation.

Representative HOLIFIELD. The Chair has informed Dr. Tompkins and Mr. Hollister that they have the privilege of touching me on the shoulder and asking questions of any witness. They certainly do have that privilege. It was announced at the beginning of the meeting, and we certainly intend to allow them that privilege.

Mr. Hollister, would you like to ask some questions of Dr. Muller before he leaves the stand?

Representative PRICE. Before he does, is Dr. Muller's paper before the National Academy of Sciences included as part of the record?

Representative HOLIFIELD. Dr. Muller, Mr. Price's question was,

have you presented your paper that you were to give at the Geneva Conference as part of the record of your presentation?

Dr. MULLER. I had not intended to do so. I would like to present something more recent—two things in fact—one short paper, Potential Hazards of Radiation, which is now in press in the journal Excerpta Medica published in Amsterdam. It is six typewritten pages with some references.

Then a little statement that I gave out last October 20, 1956, that I think I could read. It is very short.

So devastating would be the damage done to both present and future generations by the nuclear explosions which any global war is likely to bring, that the great issue of today is not that of the relatively minor damage produced by mere tests of H-bombs, but that of taking all steps we safely can, such as the mutual discontinuance of these tests, which will tend to lessen international tensions and bring us nearer to all-round armament control. Unless this control is achieved in the short time open to us before thermonuclear weapons have become available to more countries still, and before intercontinental missiles have become a reality, we will find ourselves in a situation even more ungovernable and menacing than that of today.

I also wish to introduce a paper in the report by the World Health Organization study group on the effect of radiation on human genetics (see appendix, p. 1728). This report of the World Health Organization is being presented to the U. N. Committee on Radiation Damage and will be published next month sometime, it is expected. I have a copy of the paper of mine of that report here to include.

Representative HOLIFIELD. Thank you very much. Without objection they will be received.

(The document referred to, together with an article entitled "How Radiation Changes the Genetic Constitution" by Dr. Muller, follow:)

POTENTIAL HAZARDS OF RADIATION [1]

(By H. J. Muller, Indiana University)

Evidence has in recent years been accumulating for the broad conclusion that the great majority, if not all, of the damaging effects on life and health evoked by ionizing radiation are results of permanent changes produced in the genetic material: the chromosomes or their contained genes. These changes, when occurring in the genetic material of the germ cells, reach expression through reduction in the number of functional germ cells (infertility), increased mortality of zygotes of the first and subsequent generations (dominant lethals and detrimentals), and, in general, the alteration of one or more hereditary characteristics, that thereafter are transmitted in their new form (mutations).

Our knowledge of the nature of these effects, and of their manner of production, has been derived in the first place from studies of the descendants of exposed individuals, checked by cytological observations of cells derived from exposed germ cells. However, there is increasing ground for the inference that ionising radiation produces changes in the genetic material of the somatic cells like those in the germ cells, and that it is these chromosomal and gene changes in the somatic cells that form the basis of most of the damage to the exposed individual himself, such as erythema and the various other aspects of radiation sickness, shortening of the life span, diverse malignancies, etc.

The primary changes in the genetic material, as disclosed by cytogenetic investigations on widely different forms of life ranging from viruses and bacteria to fungi, flowering plants, insects and mammals, may for convenience be divided into two groups. These are the *chromosome breaks*, that result in fragments the broken ends of which tend to unite with one another either in the old or in new arrangements, and the *point mutations*, that involve alterations at very localized positions on the chromosomes and are inherited according to Mendelian principles. It would take us too far afield here to discuss the proposi-

[1] Slightly modified version of article in press in June 1957 issue of Excerpta Medica (Amsterdam).

tions that there may be a fundamental similarity between the changes of these two groups, that they may integrade with and even overlap one another, and that, at any rate, the classification into one or the other group is in many cases uncertain. However that may be, the distinction remains of practical importance.

It is the point mutations which, although the more elusive of the two types of genetic changes, do the most harm in the long run. Even though evolution has come about by the natural multiplication of the very infrequent advantageous point mutations, the vast majority of them, whether arising naturally or induced by radiation, are of a detrimental nature, as is only to be expected of "blind" changes. Yet, contrary to popular opinion, mutations giving rise to conspicuous abnormalities, monstrosities, or freaks, are a great rarity, even after heavy doses of radiation. The point mutations induced in animal material by ionizing radiation have been found to be similar in their range of types and in the relative frequencies of those having different kinds of visible expression ("phenotype") to the naturally arising mutations, although the distribution of relative frequencies from gene to gene may be somewhat different for the two groups.

In considering the expression of a mutant gene we must distinguish between that which it has when homozygous, i. e. when inherited from both parents alike, and when heterozygous, i. e. from but one parent (the other having supplied a normal gene). Many mutant genes (possibly as many as one-fifth, as indicated by work on fruit flies) have such drastic effects when homozygous as to unconditionally kill the individual prior to maturity: these are the "lethals." The great majority of the remainder, when homozygous, cause some degree of impairment, even though relatively few of them give rise to readily visible abnormalities. In heterozygous condition their expression is usually much less pronounced than in homozygous condition and is very seldom recognizable; hence most mutant genes are termed "recessive." Yet even when heterozygous there is usually some slight, statistically important impairment of the capacity to live and reproduce. Hence, since the mutant gene is regularly transmitted to subsequent generations, it nearly always results, eventually, in the extinction (genetic death) of the line of descent carrying it, and this usually happens before the gene has had an opportunity to become homozygous.

These "genetic deaths" are seldom identifiable as such because the heterozygous individuals that suffer them show so little recognizable impairment. They represent the price paid by any population in preventing an unlimited accumulation of mutant genes within it. Studies on the frequencies of natural mutations in Drosophila, the mouse, and man, and of the effects of inbreeding in man, agree in indicating that each person carries on the average, mainly in heterozygous condition, at least four times as many mutant genes as would have been enough to kill him outright if they had been homozygous. It is further indicated that, in the mainly heterozygous condition in which the mutant genes actually occur, they tend, by their cumulative action, to cause the genetic death of at least 1 person in 5.

When the mutation rate is raised by exposure to radiation the frequency of genetic death is correspondingly raised, over a number of generations that is inversely proportional to the degree to which the mutational damage is expressed in the individual's of any given generation. Russell's studies on the mutations of 7 genes in mice show that some 30 r. delivered to the immature germ cells constitutes the "doubling dose," in that it induces in them as many mutations as arise naturally per generation. It is unlikely that in man the doubling dose is more than twice as high, and it may even be somewhat lower than in the mouse. At any rate, the correctness for man of this order of magnitude is indicated by studies of Turpin and Lejeune and of Macht and Lawrence, and is not contradicted by the lack of statistically significant findings in the studies made in Japan by Neel and Schull.

Since there is much evidence indicating a linear relation between the radiation dose and the frequency of the induced point mutations, even at extremely low doses, and the exactly cumulative nature of these radiation effects, it becomes possible to arrive at probable estimates of the minimum damage done to subsequent generations by any given chronic or acute exposure of parents. In view of the dearth of conspicuous abnormalities, one of the best overall measures of

this damage lies in a measurement of mortality, expressed for instance as length of life. The criterion has recently been used by Russell in his demonstration that neutrons applied to male mice cause a shortening of the average life-span of their progency that is about as great as that caused in the directly exposed individuals: nearly 0.1 percent of the life-span per rep. Since, however, the effects on the progeny are likely to reappear throughout scores of generations before being terminated by means of genetic deaths, the total damage to the descendants is many times greater than to the exposed individuals.

Chromosome breaks, like point mutations, are induced with a frequency directly proportional to the total dose of radiation, regardless of how concentrated or dispersed the treatment has been. Some of the rearrangements of chromosome parts result from single breaks, and some from two or more breaks lying in the course of the same ionizing particle. The frequency of either of these types of rearrangements, like that of the individual breaks, varies directly as the total dose, regardless of its distribution in time. Other rearrangements, that result from a combination of fragments derived from independent breaks occurring within the same few minutes, have in consequence of this mode of origin a frequency that is insignificant when the radiation has been of low intensity but that rises rapidly with the intensity, approximately as its square, and that becomes of major importance at high dose rates. Thus chronic or repeated low exposures give rearrangements that are linearly related in frequency to the total accumulated dose, while higher dose-rates give disproportionately numerous effects.

A cell in which one or more chromosomes have been structurally changed by breakage will continue to function normally until cell division occurs. At that time the altered chromosomes often give rise to chromatin bridges that connect the daughter nuclei, interfere with their further multiplication, and ultimately result in death of the affected cell line. In the absence of a bridge, the daughter or descendant cells may come to lack parts of chromosomes and/or to have other parts in excess, and the resulting unbalance of gene proportions ("aneuploidy") tends to impair and even kill the descendant cells. Happening in the germinal line, these phenomena are expressed as infertility of the exposed individuals, and as lethality among embryos of later generations.

The chromosome damage, leading to postmitotic cell impairment and death, is also induced in somatic (body) cells. It provides an interpretation of such phenomena as the "law of Bergonie and Tribondeau" (relating the degree of tissue damage to multiplicational activity), the radiation death of individual somatic cells in tissue cultures (as in work of Puck and Marcus), and the delayed production of minute cataracts in irradiated lenses of the eyes. That it is the chromosomes rather than the protoplasm of cells which are ordinarily the seat of the more significant radiation changes, leading to cell death, has been shown in numerous studies, among them those of A. R. Whiting, Zirkle and Bloom, and Ulrich. It is only when a given number of cells has been destroyed within a given space and time that certain visible symptoms appear, such as reddening of the skin, reduction in number of white blood cells, intestinal hemorrhage, etc. However, there is no threshold for the individual cell effects, and analyses such as that of Quastler are increasingly implicating them as the basis of the clinical manifestations.

It is almost certainly through the individual cell deaths and impairments that minute doses of radiation, long continued or repeated, exert their action in shortening the life-span of the exposed individual. This effect, first analyzed by Boche and then by Sacher, has been calculated to cause a reduction in length of life of the order of several days for every roentgen unit received by the body as a whole during a person's lifetime.

On the other hand, leukemia and some other malignancies, the induction of which may also be linearly dependent upon radiation dose, are considered by geneticists as being more probably results of point mutations in somatic cells than of chromosome breaks. From the conclusions of Lewis it may be calculated that for a population of 160,000,000 with a lifespan like that in the United States each absorbed roentgen of whole-body radiation would result in some 10,000 cases of leukemia during their lifetime, while one-tenth the "maximum permissible dose" of strontium 90 would result in some 55,000 cases.

The present population of the United States has been reckoned to receive, on the average, some 5 r. of radiation to the gonads from medical exposures alone before the age of 30 (see Laughlin and Pullman) but the amount from all diagnoses and treatments may well be double this (see Schubert and Lapp). About 3 r. are received from the natural background radiation. The amount

from atomic test fallout is as yet much less, and is said to be of the order of .1 r., although atomic warfare, or insufficient precautions in the peacetime use of atomic energy, could raise it enormously. The present exposure of Western populations, caused largely by fluoroscopy and by roentgenograms of the lower trunk, is not enough to cause concern in regard to shortening of life of the exposed generation, but its effect on future generations must be a good deal greater. The same consideration applies to occupational exposures. It has led to the recent recommendations for intensification of radiation precautions promulgated by the National and International Committees on Radiation Protection, and the committees on the genetic effects of radiation of the National Academy of Sciences (United States), the Medical Research Council (Great Britain), the World Health Organization, and the United Nations. It has recently been reflected in increasing activity in this direction in medical and dental circles.

How Radiation Changes the Genetic Constitution

H. J. Muller

Dr. Muller, professor of genetics at Indiana University, prepared the following paper for presentation at the United Nations Conference on the Peacetime Uses of Atomic Energy, at Geneva. Although the paper was not given orally, it will appear in the published proceedings of the Conference.

The changes in the genetic constitution produced by ionizing radiation may for convenience be classified into two major groups: *chromosome aberrations* and *point mutations*.

The chromosome aberrations consist of losses and additions of whole chromosomes or chromosome parts and/or alterations, called structural changes, in the alinement of chromosome parts. Structural changes are caused by the breakage of one or more chromosomes at two or more points, followed by the junction of the fragments at their broken ends, so as to form a new arrangement; that is, a new linear sequence of their component hereditary particles or genes.[1]

Point mutations are changes confined to regions of the chromosomes so small that no loss or addition or change in arrangement of genes can be demonstrated by microscopic examinations or breeding tests. Since structural changes range from "gross" to those so minute as to be at the limit of being detectable as such, there are doubtless other cases of substantially the same kind, but below that limit of size, which become included among the point mutations. However, there is reason to infer that many of the point mutations produced in animals by radiation are not of this kind, but involve changes within the individual genes, and are therefore to be considered as "gene mutations." By this it is meant that these changes are restricted to genetic elements too small to be divided either by the process of normal hereditary recombination (crossing over) or by that of gross structural change. This seems to be true also of the great majority of genetic differences that exist naturally between individuals of the same species; that is, they appear to have arisen as gene mutations.

CHROMOSOME ABERRATIONS

The chromosome aberrations produced by radiation in the cells of somatic tissues that replenish themselves by proliferation cause necrosis in much of the tissue descended from these cells and abnormality in much of the surviving descendant tissue. This constitutes a major source of delayed radiation damage, some of it never repaired, in the exposed individual himself. The same series of events, occurring among the immature germ cells of the exposed individual, can result in his or her partial or complete sterility. Among mature and nearly mature germ cells, especially spermatozoa, there is a much higher incidence of induction of these chromosome changes, for any given dose of radiation, than among immature germ cells or somatic cells.[2] Recent evidence[3] confirms the inference[1] that this peculiarity depends upon the chromosomes being in a condensed (tightly spiralized) condition and that it therefore applies also to cells that are in mitosis at the time of irradiation.

Mature sperm or eggs in which chromosome aberrations (actual or potential) have been induced, function in fertilization, but many of the resulting embryos die in consequence of their abnormal chromosome content. Other embryos, in which there has been gross structural change without excess or deficiency of chromosome parts, develop into normal adult individuals. However, when these seeming normals reproduce, recombination occurs between the structurally changed chromosomes derived from one parent and their normal homologues derived from the other parent. In consequence of the nonmatching linear arrangement of the genes from the two parents, about 50 percent of the germ cells now produced have excesses and/or deficiences of chromosome content. These germ cells usually function, but give rise to embryos (of the second generation after exposure) which die in utero at an early stage.[4] This mortality of embryos tends to be repeated over an indefinitely long series of generations. For half of the surviving embryos of such a line of descent, although not themselves containing the lethal excesses or deficiencies, have the grossly changed linear arrangement of genes that, by recombination, again gives rise to these effects.

In modern human populations, there is a tendency to compensate or even overcompensate for reductions in the frequency of viable births, by purposely increasing the number of pregnancies.[5] Hence damage of this kind, once induced, does not tend to die out rapidly but may even spread.

Fortunately there are several factors which serve to limit the frequency with which these cases of inherited abortions are produced. One is the fact that the period spent by male germ cells in a mature or nearly mature state averages, at the very most, a few months, whereas they usually spend some 25 years or more—well over 100 times as long—as immature germ cells, relatively insusceptible to the induction of chromosome aberrations. Although the relative lengths of the corresponding periods for female germ cells are not well established, the germ cells are, even when nearly mature, much less susceptible than spermatozoa to the induction of the gross aberrations that cause inherited abortion.[6] It may be concluded that more than 99 percent of the germ cells which function after a given exposure of limited duration (comprising only a few days or weeks) were at the time of that exposure in an immature stage, relatively insusceptible to the induction of chromosome aberrations. In them, aberrations of all kinds were induced with far lower frequency than point mutations.

Even in the less than 1 percent of germ cells that are exposed to radiation of beta or gamma type during their susceptible stage, gross structural changes of chromosomes will be produced at a low frequency, relatively to point mutations, unless the total dose of radiation received in that period is fairly high, of the order of a hundred or more r. (roentgen) units. This is because the

---

[1] See footnote, p. 1069.

[2] However, some immature germ cell stages are much more susceptible to chromosome alteration than they appear to be when judged by the frequency with which such alterations are found later, on analysis of offspring derived from the cells that had been exposed while immature. This is because the descendant cells derived from those immature germ cells in which the chromosomes had been altered so often die out, and have their places taken by compensatory multiplication of descendant cells derived from those immature germ cells in which the chromosomes had not been altered. This consideration does not apply in the case of point mutations. (Note added October 5, 1955.)

[6] G. D. Snell and F. B. Ames, Am. J. Roentgenol. Radium Therapy 41: 248–55 (1939).

production of these aberrations requires at least two chromosome breaks, and these are usually produced independently, by the tracks of different fast particles. On account of being in this sense double or multiple events, these aberrations vary in their frequency according to an exponent of the dose of radiation higher than one (commonly, about 1.5).[1] On the other hand, the point mutations vary as single events, according to the dose itself. Thus, as the dose is diminished, they do not drop off as fast as the structural changes do, and the latter become rare, relatively to the former.

It follows from the above considerations that inherited abortion caused by structural change is a relatively insignificant danger even in the case of a large dose of beta or gamma radiation that has been received in small fractions of not more than a few r. per month. If the amount received in any month is higher than this, however, measures should be taken to avoid this damage. These measures would consist in the prevention or avoidance of conception until the passage of several months after the high exposure. With a very high dose, however, all but the first month of this period would be sterile anyway.

When the exposure has been to alpha or neutron radiation, the production of gross structural changes tends to vary with the dose itself instead of with a higher exponent.[7] This is because both the breaks participating in such an aberration are usually produced by activations arising from the track of the same fast atomic nucleus. In consequence, both of this proportionality of the frequency of structural change to dose with this type of radiation, and of the fact that the more densely crowded activations from such radiation are actually more efficient in breaking the chromosomes, much lower doses, in reps, of neutrons or alpha rays than of gamma, beta, or X-rays give significant numbers of structural changes. Hence, the rule of not reproducing within some months after exposure should be applied in this case of much lower doses when the radiation has been of these types. In order to gage how low this limit should be placed, it should be taken into consideration that even 5 reps of neutrons, applied to spermatozoa, may be estimated to induce inherited abortion, based on gross structural change in some 1 to 6 among every thousand viable individuals derived from these spermatozoa.[8]

The frequency of natural occurrence of gross structural changes giving inherited abortion has not been studied extensively in mammalian populations, but it is known to be low. The highest recorded figure[9] is about 6 percent. Among offspring from spermatozoa treated with 500 r. X-rays, 25 percent have been reported by 2 observers.[10]

CHARACTERISTICS OF NATURAL POINT MUTATIONS

Among the genetic changes induced by exposure to radiation from artificial sources the point mutations are far more frequent and significant that the chromosome aberrations. Among the genetic changes that arise from natural causes (those somewhat misleadingly referred to as "spontaneous") the point mutations are still more frequent and important, as compared with the chromosome aberrations. Any ordinary population contains a large accumulation, or "load," of these natural point mutations, which have arisen in the course of many past generations. If any new point mutations are induced by radiation these are added to this already existing load of mutations. They thereupon become lost to view among the latter, in the sense that, with rare exceptions, the origin of any individual point mutation cannot be traced to the radiation. Thus, in order that radiation mutations may be viewed in due perspective, certain salient facts about the natural mutations should first be passed in review.

Natural point mutations occur sporadically. They are not individually controllable. Any such mutation may be thought of as resulting from an accidental ultramicroscopic encounter between a gene and some atom group, particle, or photon to which the gene happens, under the circumstances, to be vulnerable. It is probable that, on occasion, instead of the original or "mother-gene" becoming

altered, the accident causes a misstep in the construction of the "daughter-gene," but the effect is much the same as if the old gene had itselm mutated. In either case, point-mutational changes are permanent. This implies that the changed gene tends to be very stable, as the original gene was, and that in reproducing it continues to give rise to daughter genes like itself, that is, in this case, of the new type. Thus it "copies itself" through an indefinite succession of generations.[11]

The frequency of mutations in general is influenced, however, by many conditions. Thus, cells in certain developmental stages have mutations occurring more frequently in them, in other stages less frequently.[12] There is some evidence that markedly detrimental disturbances in the cellular biochemistry, of whatever nature, tend to favor the occurrence of mutations, while the functioning of the cell within its normal range is associated with a low mutation frequency. Certain special substances, such as the mustard gas series, some organic peroxides and expoxides, and triazine are so conducive to mutation that they have been termed "mutagens."[13] Some of them can in fact be used to induce mutations at about as high a frequency as with radiation. When the distribution of relative frequencies of the different types of mutations induced by one mutagenic agent is compared with that induced by another, or with that of spontaneous mutations, considerable differences are often found, even though most types of mutations produced by one agent are also produced to some extent by any other, and also arise spontaneously but at a lower rate.[14]

The partial selectivity of action of mutagens does not give evidence of being of such a nature as to result in the mutations produced by a given agent, or under given conditions, being better adapted, as a group, for life in the presence of that agent, or under those conditions, than are the mutations which arise under other circumstances. That is, mutations arising independently of radiation like those produced by radiation are, so far as the organism is concerned, accidents, not adaptive responses. There is evidence indicating that the organism has, through a long period of evolution, been selected for the maintenance of biochemical operations which give it as low a frequency of "natural" mutations as can practicably be attained just as it has been also selected to react in such ways as to minimize the occurrence of other accidents.[15]

It is entirely in line with the accidental nature of natural mutations that extensive tests have agreed in showing the vast majority of them to be detrimental to the organism in its job of surviving and reproducing, just as changes accidentally introduced into any artificial mechanism are predominantly harmful to its useful operation.[11] According to the conception of evolution based on the studies of modern genetics, the whole organism has its basis in its genes. Of these there are thousands of different kinds, interacting with great nicety in the production and maintenance of the complicated organization of the given type of organism. Accordingly, by the mutation of one of these genes or another, in one way or another, any component structure or function, and in many cases combinations of these components, may become diversely altered. Yet in all except very rare cases the change will be disadvantageous, involving an impairment of function.

It is nevertheless to be inferred that all the superbly interadapted genes of any present-day organism arose through just this process of accidental natural mutation. This could take place only because of the Darwinian principle of natural selection, applying to the genes. That is, on the rare occasions when an accidental mutation did happen to effect an advantageous change, the resultant individual, just because it was aided by that mutation, tended to multiply

more than the others. By the continuance and repetition of this process, the type that had been normal became supplanted by other types, that were at least better adapted for life in certain particular environments, in in certain ways. Thus, the mutant gene of the previous era became the normal gene of today, and the whole system of genes of the species tended to become even more differentiated and highly organized. Yet at each stage the great majority of new mutations, if examined before being put through the sieve of selection, must have been detrimental to life or to reproduction, as they are today in all species studied, no matter what the degree of advancement of the species.

As important for the survival of a species as the differential multiplication of the few better adapted mutants is the reduction in number and eventual dying out, in competition with the "normal" type, of the much more numerous mutants that are less fit than the normals. Since each generation supplies a fresh crop of these mutations, to be added to those inherited from earlier generations, it is obvious that without this negative selection the system of genes would undergo continued decay. Thus after a time it would become completely heterogeneous, disorganized, and degenerate.[10] In the past, only natural selection has saved it. This selection makes it practically inevitable that any detrimental mutation, no matter how small its harmful effect, will in the long run become limited by tipping the scales against some descendant who carries it, causing his premature death or failure to reproduce.

However, this dying out of the unfit mutants is in most cases rather long delayed. One reason for this delay is the fact that mutant genes are in the great majority of cases heterozygous, that is, present in individuals who have received the corresponding normal gene from their other parent, and that in such a situation the normal gene usually produces most of the effect. The normal gene is for this reason said to be "dominant," and the mutant gene "recessive," even though the mutant is seldom completely without expression when heterozygous.

Another reason for the delay in the dying out of mutant genes lies in the fact that even in those relatively rare individuals who are "homozygous" for a given mutant gene, by reason of having inherited that same gene from both parents, the amount of abnormality is often not very great. Hence, even in this situation the gene usually confers a much less than 100 percent risk of premature death, or of failure to reproduce. It may be noted in this connection that the idea that most mutations are monstrosities or freaks is a popular misconception. In fact, only a tiny minority of mutations cause very conspicuous visible abnormalities.

CALCULATION OF NATURAL MUTATIONS PRESENT IN A POPULATION

The total number of point mutations (or, more correctly, of point-mutant genetic conditions) present in any population at a given time is a product of two interacting numerical factors. The first factor, *a*, is the total number of new point mutations that arise in one generation. The second factor, *b*, to be multiplied by the first, is termed the persistence. It represents the total number of individuals of successive generations by whom, on the average, any given mutation, present at first in one individual, comes to be inherited.[16] This same relation holds for mutations of any particular type as well as for the totality of mutations.

Obviously *b*, the persistence, depends upon the ability of the individuals carrying the mutation to live and breed, as compared with normal individuals. If, for simplicity, we assume the whole population to be of stable size, then *b*, for the average mutation, or for any given type of mutation, is the reciprocal of *c*, the average chance that an individual who has inherited it will be killed prematurely, or will fail to reproduce, as a result of the one or more functional impairments occasioned in him by that mutation. In getting this average chance of elimination, *c*, we must estimate the relative frequencies of individuals heterozygous and homozygous for the mutation, and multiply the chance of elimination of each of these types, taken separately, by its relative frequency. When this is done it is found that usually, despite the much smaller

[16] H. J. Muller, Amer. J. Human Genet. 2: 111–76 (1950). H. J. Muller and S. L. Campbell, unpublished data. (This reference was omitted from original. Note added October 5, 1955).

detrimental effect in the heterozygous individuals, their relatively large numbers cause most of the eliminations, and most of the total genetic damage to the population, to occur in this group. Thus, in most cases, the homozygous group can for practical purposes be ignored.[16]

In order to apply this method of calculation to human populations we must first have estimates of *a* and *b*. At present such estimates are very indirect, and serve only to indicate a broad range, within which, somewhere, the actual value is probably located. The fruitfly *Drosophila* has thus far been the only organism in which anything like a direct approach has been made to an observed value for either *a* or *b*, and even here the results are subject to very large errors. In this material it can be estimated that, in a population of 100 million, *a*, the number of new mutations arising naturally per generation that becomes transmitted to the next generation, is on the average at least 8 million, and that *b*, the persistence or average number of individuals of successive generations which finally come to inherit any given mutation, is considerably more than 20 and probably more than 40. This makes *ab*, the number of mutations carried by the population of a hundred million in any given generation, probably more than 320 million, that is, probably more than three per individual.

The estimate of *a* for *Drosophila* was obtained by first taking the observed frequency, 0.18 percent, with which "recessive" fully lethal mutations (those that invariably kill homozygous individuals) usually arise in the X chromosome per germ cell per generation when no mutagenic treatment is used.[12] This figure was then multiplied by 6, the ratio of recessive lethals in all the chromosomes to those in the X chromosome. This figure had to be obtained from experiments in which radiation was applied to spermatozoa.[17] The product, 1.08 percent, representing all lethals, was in turn multiplied by 4, the ratio which all mutations detrimental enough to have been detected by a given technique were found to bear to fully lethal mutations. This figure 4 also was based on radiation mutations.[18] Finally, the second product, 4.3 percent, was multiplied by 2, because each individual results from 2 germ cells, and the resultant percent, 8.6, was multiplied by 100,000,000, the number assumed to exist in the population.

That the application of the ratio 6, derived from radiation work, to natural mutations is legitimate has been shown by special tests. However, among natural mutations as a group, the ratio of all mutations to lethals is probably a good deal higher than 4, the ratio found among mutations produced by irradiating spermatozoa. For the radiation mutations include a greater proportion of structural changes and these are more often lethal. This is one reason why the final figure for *a* is very conservative. The other reason is that the methods of detection used failed to find mutations that produced less than about 10 percent risk of premature death, even if they caused considerable infertility, and such mutations may have been relatively numerous.

The figure for *b* is based on tests, carried out independently by two groups of investigators,[16, 19] to determine how much risk of premature death is conferred by a "recessive" lethal mutation when it is heterozygous. In both cases an average figure of about 3 percent to 5 percent risk of death was obtained. This would result in only 1 heterozygous individual among some 25 being killed and would hence allow the average lethal a persistence of 25. That is, it would tend to be passed on to some 25 individuals, on the average, before it died out. Since, however, a considerable majority of mutations are not so detrimental as to be fully lethal when homozygous, and most of them are probably not even 50 percent lethal when in that condition, the figure of 1 in 25 (4 percent) for the risk of death when heterozygous must be considerably higher than that holding for the average mutation, and the persistence, being the reciprocal of this, would be considerably higher than 25. That is why 40 was used as a better guess for *b*, but the observed distribution of mortalities indicates that even it is likely to be too low.

Before we can convert our figure *a* for newly arising mutations in *Drosophila* into a corresponding figure *a* for man we must obtain some indication of the

ratio of mutation frequency in *Drosophila* to that in man. As yet the only line of approach to this problem lies in a comparison of the frequencies, in the two species, of natural mutations that produce certain specific effects, and that may be inferred to occur at given highly limited positions in the chromosomes. Although the evidence of this kind is meager and imperfect, there is enough of it to show that in *Drosophila* a mutation of any one specific type, located in a specific chromosomal position (so as to give rise to what is technically known as an "allele" or "pseudo-allele" of some preexisting mutation) arises, on the average, with a natural frequency of between 1 in 100,000 and 1 in 300,000 germ cells, the most likely figure being about 1 in 200,000.[20] In mice there is little published data of this kind as yet but it would indicate a figure in the range between 1 in 40,000 and 1 in 400,000 or, most likely, about 1 in 140,000.[21] In man, an estimate of between 1 in 50,000 and 1 in 100,000 has been arrived at, on the basis of a much larger amount of data than in either mice or *Drosophila*, but the uncertainties of the methods used in man are much greater.[22] These apparent differences in mutation frequency between the three species may well correspond to the different numbers of cell divisions which take place in their respective reproductive cycles, since these numbers for flies, mice, and men are related about as 1: 1.5: 2. At any rate, it is likely that the average frequency of mutations of any specific type in man is higher than in *Drosophila*, probably from 2 to 4 times as high. To be conservative, we will adopt the lower figure, 2.

It is, however, likely that the ratio of frequencies of specific mutations in man to those in the fly would not be nearly as high as the ratio of total mutation frequencies in man to those in the fly. For man, and mammals in general, give evidence of having a more complicated organization, all told, than the fly, especially when the complications of the nervous system are taken into account. Mammals may therefore be expected to have a more complex germ plasm than flies, one in which a larger number of different kinds of mutations of specific types can occur. This agrees with existence of a larger amount of the genetic substance, polymerized deoxyribonucleic acid, in mammalian than in fly chromosome sets. Therefore we are in all probability obtaining a low minimal figure for a in man if we multiply the *Drosophila* a by only two.

For the value of b in man or other mammals there is as yet little basis for a decision. The existing indications point strongly to the conclusion that natural mutations in mammals in general, including man, are, as in *Drosophila*, prevailingly recessive, yet not completely so. Moreover, they certainly include a fairly abundant group of "recessive" lethals, but it is probable that mutations having a lesser degree of detriment are more frequent than lethals. At this preliminary stage of our knowledge of the subject, then, we have little ground for using a markedly different value of b for mammals than for *Drosophila*.

The figure of about 6.5 is thereby arrived at as a minimal one for the content of recessive, definitely detrimental mutations (including lethals) per individual human being. In a preliminary calculation using related methods, the figure 8 was arrived at.[16] These estimates, as recently shown by Slatis,[23] can be checked in a more direct way. The method consists in observations of the frequency with which homozygous individuals, showing the more definite abnormality often associated with a homozygous mutation, appear among the offspring of marriages between close relatives. Application of this technique has led Slatis, very tentatively as yet, to the figure 8 as the most probable present approximation to the number of natural mutations of the kind in question for which a person is, on the average, heterozygous. This method now needs to be applied on a much larger scale but the present result is enough to be reassuring, in indicating that our mode of calculation is giving figures of the right order of magnitude.

It should be emphasized that in these calculations we are dealing only with these mutations which are detrimental enough to give a "sizable" risk of genetic extinction by way of premature death; that is, one as great as about 0.5 percent in the case of the heterozygous individual, or 10 percent in the case of the homozygous one. We do not know how many mutations arise which are less harmful than this, or which cause extinction mainly by their interference

with reproduction, not with life itself. However, even if there are relatively few, those few which have an average grade of detriment within the same order of magnitude as the frequency of their origination by mutation, will accumulate so as to be inordinately numerous in the population. They will provide a very considerable proportion of the superficially observable genetic variability. Moreover, the frequency of the different types of mutations of this group will differ greatly from region to region, in response to differences in the conditions of selection, as well as to random influences.

Since the frequency with which mutant genes of any given degree of detrimental effect exist in the population at any one time is the product *ab*, where *b* is inversely proportional to *c*, the degree of detrimental effect, it is evident that the existing mutant genes have a distribution, with respect to their harmfulness, very different from the distribution to be found on examining mutations as they arise. For, among the mutant genes as they exist in the population as compared with them at their origination, the less harmful ones are (in inverse proportion to their harmful effect) more numerous than the more harmful ones. For that very reason each slightly harmful mutation that arises tends to cause as much detriment to the population as a whole in the end as each drastically harmful or lethal mutation does, since it compensates for its relatively small degree of harm by afflicting correspondingly more individuals. In consequence, the total amount of genetic damage done to a population by mutations is much more closely proportionate to the total frequency of mutations arising per generation (a/N, where N is the number of individuals in the population) than to the frequency of mutations existing in the population (ab/N).[24] If a is raised or lowered, however, it may take scores of generations before its changed value becomes proportionately reflected in the altered average fitness or mutational load of the population. A similar lag occurs if b is altered, as happens when the rigor of selection is increased or decreased.

CHARACTERISTICS OF POINT MUTATIONS PRODUCED BY RADIATION

In the plant material studied by Stadler,[25] evidence was obtained, based on the intensive study of a few types of mutations, that the great majority of apparent point mutations induced by radiation probably consisted of losses of a small section of a chromosome including more than one gene, unlike what was usually true of the natural mutations. In the animal material best studied with reference to this question, that of *Drosophila*,[26] there is evidence that such "sectional deficiencies" do comprise a good deal larger proportion of the point mutations obtained by irradiation of the mature germ cells than of the point mutations arising naturally. However, the apparent point mutations produced by irradiation of immature germ cells of *Drosophila* do not include substantially more that on further analysis prove be be demonstrable "sectional deficiencies" than are found among the natural mutations. Moreover, the characteristics of the effects produced on the individual, both in *Drosophila* and mice,[10, 27] also indicate that a large proportion of these radiation-mutations are as truly changes within the genes as are the mutations of natural origin.

In general, then, in the animal material, the radiation-mutations strongly resemble the natural ones. Practically all types of natural point mutations that have been looked for in extensive irradiation experiments have been found to be produced by radiation also. Like natural mutations, of course, the great majority, although not quite all, of those produced by radiation, are detrimental. Moreover, the great majority have far less dominance (i. e., less expression in the heterozygous individual) than the normal genes from which they arose. Once arisen, the radiation mutations, like the natural ones, are permanent, reproducing themselves as such.[28]

Just which mutation is produced by radiation on a given occasion is of course a matter of "accident," as is true of natural mutations. However, the total frequency of the mutations produced by a given dose of radiation varies to some extent with the accompanying conditions, as in the case of natural mutations, although the conditions in question are to some extent different ones in the two cases. The conditions which influence the production of point mutations by radiation include genetic differences, differences in cell type or stage, differences in metabolic reactions, and (a category overlapping the previous one) differences caused by the application of special chemical or physical treatments.

For the most part, the same influences have been found to promote or hinder the action of radiation in causing point mutations as in causing structural changes of chromosomes. For example, chromosomes in condensed stages are more susceptible to the induction of changes of both types. Some findings of interesting differences in this respect have been reported, however. Among these are the observations that sperm cells of *Drosophila* several days prior to their release, and therefore perhaps in the spermatid stage, are much more susceptible than mature spermatozoa to the production of radiation of structural changes, but not of point mutations.[29]

In accordance with the view, first proposed by Rapoport[30] on the basis of chemical work by Fricke,[31] that the mutagenic action of radiation is exerted via the production of actively oxidizing radicals or molecules, it is found that radiation mutagenesis of both major types is positively correlated with the amount of free oxygen present at irradiation. Physical or chemical influences which appear directly or indirectly to increase or decrease the abundance of oxygen available for conversion into mutagenic radicals influence correspondingly the frequency of mutations produced. There is, to be sure, evidence indicating that not all the mutagenic action of radiation takes the same pathway, and that some of it may be quite unconnected with oxidation. But, however that may be, the above and other findings, by demonstrating the conditional nature of radiation mutagenesis, constitute a disproof of the target hypothesis of such mutagenesis, at least in the simplified form in which it had sometimes been applied.[32] Moreover, these findings are of considerable practical value in having led to the working out of treatments, described in other sections of this conference,[33] which give hope of affording significant protection against the mutagenic action of radiation. The fact that certain treatments, even when given after irradiation aid in such protection, is especially noteworthy, both from a theoretical and from a practical standpoint.

In material of varied kinds, but more especially in *Drosophila*, there is good evidence that over a considerable range of dose (in *Drosophila*, from some 50 r. to more than 1,000 r., a more than twentyfold range) the frequency of point mutations (like that of chromosome breaks) is directly proportional to dose.[34] Moreover, they are independent of the timing of the dose, over an enormous range, provided cellular conditions are held constant.[35] Below 25 to 50 r. the mutation frequency is so low that it has hitherto been impossible to obtain sufficient data, and above 1,000 or 2,000 r. the determination of frequency may be interfered with by a selective elimination (through chromosome aberations) of the cells that happened at irradiation to be in a more susceptible state.[36] Since, however, in the work with low doses and low time-rates of delivery of gamma radiation the germ cells of some series were traversed by only one electron track in a period of a half hour or more, on the average, and still showed a frequency of mutations proportional to the total dose, there is reason to infer that no dose or intensity of such radiation is without its proportionate production of point mutations. Moreover, if this is true of gamma radiation it must be at least as true of radiation producing tracks more densely crowded with ionizations.

Despite the equal mutagenic efficiency of different doses and dose rates of ionizing radiation, it is not necessary to infer that a point mutation or a break is ordinarily the consequence, direct or indirect, of a single activation or even of a single ionization. For all the ionizing radiation studied, has some of its ionizations produced in clusters of minute diameter. If two or more ions commonly cooperate mutagenically, however, it might be thought that this would become evident by causing the frequency of mutations to vary as the square or some higher power of the dose. Yet this would not be true if those ions had to be as near together as the ones in a natural cluster, for such close juxtaposition as this would not be brought about with appreciable frequency by raising the dose and the dose rate within toleration limits.

That such cooperation in mutagenesis does occur is indicated by recent observations to the effect that fast neutrons appear to be approximately twice as efficient as X or gamma rays in inducing point mutations in the chromosomes of *Drosophila* spermatozoa,[37] and are probably a good deal more efficient still, relative to X or gamma rays, in inducing chromosome breaks.[38] Presumably alpha rays likewise would be more efficient than X or gamma rays in these respects. One possible interpretation of this higher effectiveness of fast neutrons would be provided, on the Watson-Crick hypothesis of the structure of the genetic material, by the doubleness of the fibers in which the rearrangements are produced, if we suppose that the occurrence of the mutation or break is much facilitated when both fibers are simultaneously affected.

The effectiveness of fast neutrons in inducing point mutations is actually higher than it appears to be, because intensive studies of given cases of these seeming point mutations have shown that in fact a considerable proportion of them involve a double or multiple effect within a very localized chromosome region.[39][40] This greater clustering of effects with neutrons than with X or gamma rays is to be expected, in view of the greater concentration of the ionizations in the tracks of the ionizing particles released by neutrons, provided that the mutational effects arise in close proximity with the activations that induce them. Since this clustering of effects causes many of them to be lost to

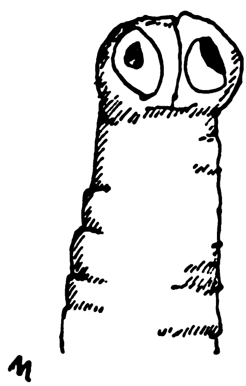
view by reason of their proximity to each other (except when special techniques of analysis are used), the mutagenic potentiality of the fast neutrons is correspondingly underrated in most experiments. So far as genetic damage to the population is concerned, however, a double or multiple effect of the given kind adds no more to the mutational load than does a single effect. Hence for present purposes fast neutrons may be regarded as no more than twice as effective as X or gamma rays in producing point mutations.

ESTIMATION OF THE TOTAL POINT MUTATIONAL DAMAGE FROM A GIVEN AMOUNT OF RADIATION

It has been noted that the important quantity in the determination of the total amount of genetic damage is not the amount of harm done to the individuals who have inherited the mutations in question but only the total number of these mutations. For a mutation doing less harm to an individual will, as if in compensation, be passed down to a correspondingly larger number of descendant individuals. It has also been noted that an approach to a direct estimation of the total number of mutations arising has thus far been made only in *Drosophila*, and that this calculation has involved the use of data from radiation experiments. This work can therefore be applied to the estimation of the total damage arising from a given dose.

The principles have already been explained whereby a minimum value for the total number of mutations is obtained by getting the number of lethals in the X chromosome and then multiplying this by 6, to get the number of lethals in all the chromosomes, and again by 4, to get the total number of mutations causing at least 10 percent detriment to life, when homozygous. (A correction is made in this calculation, based on certain tests, in order to estimate the number of point mutations without including the structural changes.) When this calculation is carried out, using the results obtained at any given dose, the resulting number can then be expressed in terms of the total number of point mutations produced by a single r. unit, by using the principle of proportionality of point-mutation frequency to dose. It is then found that this number turns out to be about 1 mutation among 2,000 germ cells per r. (that is 5×10^{-4}/r.) for X or gamma rays applied in the usual way to mature spermatozoa.[41] The more important figure, representing the result of irradiation of the more prevalent stages (gonia) of immature germs cells of adult *Drosophila*, is only a fourth to a half of this, according to the conditions. It is probable that there are even lower values for certain other immature stages of *Drosophila* germ cells, as for instance those in the embryonic polar cap.[42]



In order to obtain a figure for the total number of mutations produced by a given dose in mammalian material we may follow the procedure which we

Muller, "The Nature of the Genetic Effects Produced by Radiation," Radiation Biology (edited by A. Hollaender), McGraw-Hill Co., New York, Vol. I, Chap. 7, pp. 351–473 (1954).

[42] Z. I. Berman, Isvest. Akad. Nauk, SSSR, pp. 645–78 (1939). Helen U. Meyer, unpublished data.

adopted in the calculation of natural mutations. This involved a comparison of the mutation frequencies involving particular types of mutations, located in given positions on the chromosomes, in *Drosophila* and in mammals, and then applying the ratio thus found to the figure for total mutation frequency in *Drosophila* so as to convert it into the presumed corresponding value (a minimal one) for mammals.

Fortunately, there is available for this comparison a much more reliable body of data, for both groups of organisms, than that which we had recourse to in the case of natural mutations. The average frequency of point mutations of the kind in question in *Drosophila*, based on a study of 10 types (loci), was found to be about 1.4×10^{-8}/r. for any given type, when the radiation was applied to inactive immature germ cells (oögonia).[43] The different types seldom varied from one another in frequency by a factor of more than 2 in material abundant enough for judging this matter (that in which spermatozoa had been irradiated.

In the mammalian material, comprising irradiated spermatogonia of mice, Russell[30] has reported an average mutation frequency of about 25×10^{-8}/r., based upon 7 specific types of mutations (loci). Here the range of variation between the different types was greater than in the above *Drosophila* material, but their mean agreed well with their mode, and 4 of the 7 types conformed fairly closely with this mean. It is clear on comparison of the two sets of results that the susceptibility of the mammalian material is at least an order of magnitude higher than that of the flies, the observed factorial difference in results being 18. To obtain a minimum estimate of the total frequency of mutation in the mice we must therefore multiply by 18 the figure arrived at for gonial cells of flies. (It is of no consequence that in the flies oögonia were studied and in the mice spermatogonia, since special comparisons[44] have shown these two cell types to be alike in mutagenic susceptibility as they are expected to be.) Since the figure for the gonia of flies had a lower limiting value of 1.25×10^{-4}/r. the minimum value for mice becomes 2.25×10^{-3}/r. This is the frequency for a germ cell, not for an offspring derived from two such germ cells; for the offspring it would be 4.5×10^{-3}/r.

In performing this calculation we are, as in the case of the natural mutations, assuming that the hereditary material of mammals is no more compound than that of flies; i. e., that there is not a greater number of different specific types of mutations in mammals than in flies, despite their seemingly more complicated organisms and their larger amount of deoyribonucleic acid. The total frequency of mutations per r. may be a good deal higher than here calculated not only because of the inadequacy of this assumption but also because weakly detrimental mutations and those mainly affecting fertility rather than individual survival have not been included. Moreover, only the lower limiting value for the somewhat variable mutation frequency of fly oögonia was used. All this emphasizes the fact that our estimate is decidedly on the "conservative" side.

At the same time, it is true that the value is one for mice, not human beings. All that can be said to this is that, so long as we lack data on an organism still closer to man, it is necessary, provisionally, to base our judgments on this result, and that, since mice are so much closer to men than flies are in almost every other important respect, it would be strange if they were not closer in their mutagenic properties as well. Moreover, the factors which might be expected to cause a significant difference in the natural mutation frequencies of mice and men—their great discrepancies in length of life, size, and number of cell generations in the reproductive cycle—would not be expected to exert significant influences on the frequency with which mutations are produced in them by radiation.

The minimum figure of 4.5×10^{-3}/r. point mutations for the offspring of parents both of whom were exposed can be expressed in the form: "at least 1 induced point mutation per offspring, on the average, for each 220 r. of exposure to both parents. From this it is evident that many of the children who were conceived by Hiroshima survivors at any time after their exposure must have contained one or more mutations induced by the radiation. Similarly, children conceived

NOTE.—Only when these two papers are taken in conjunction with one another does the equal mutagenic susceptibility of gonial cells of the two sexes become evident.—H. J. M.

by parents both of whom have been exposed to the so-called "permissible dose" of 0.3 r. per week (15 r. per year) for as long as 15 years would on the average contain at least 1 induced mutation. It is probable that the same is also true of the children of many radiologists, dermatologists, and dentists.[45]

The recent study of Macht and Lawrence,[46] gives direct evidence of genetic damage in such cases and is in this respect superior to the studies made in Japan. Moreover, studies of Moeller et al.[47] show that the population in general is already receiving significant amounts of radiation from medical diagnoses. Sonnenblick [48] finds that exposures of this kind are seldom adequately controlled.

When it is considered that practically every mutation must eventually become eliminated from the population, after having—even if imperceptibly—hampered enough descendants so as finally to be a deciding cause, in the last of the line, of his premature death or failure to reproduce, then it becomes evident that practically every mutation represents a postponed disaster. Thus the genetic damage, that to later generations, caused by a given total dose is seen to be far greater than the damage to the exposed individual himself. In view of this, measures and regulations concerned with radiation protection should be based, at least in the case of persons who may later reproduce, primarily on the risk of genetic damage or, more specifically, of point mutations in their germ cells, rather than on the risk of damage to their own bodies. This would cause such measures and regulations to be far more stringent than they are at present.[49]

THE INDUCED MUTATIONS IN RELATION TO THE NATURAL LOAD

On our conservative estimate of 16 million natural mutations arising per generation in a population of 100 million, a frequency of 0.16, it would take only about 37 roentgens of gamma radiation delivered to the population to produce a quantity of new mutations equal to the new natural ones, and thus to double the mutation frequency. Our conservative estimate, however, was based on the assumption of only 1×10^{-5} as the average freqeuncy of a mutation of some specific type, involving a given chromosomal position. According to this assumption the actual data, which indicate about 2×10^{-5} as the frequency of mutations of a specific type, are misleadingly high, because of certain sources of technical error. Since, however, this is a matter by no means proved as yet it remains quite possible that the amount of radiation necessary to double the mutation frequency is 75 roentgens or higher. This is approximately the value that we used in our earlier treatments of the subject,[49] [50] in which it was assumed that the observed 2×10^{-5} frequency for mutations of a specific type was approximately correct. These considerations illustrate the considerable margins of error in any present quantitative treatments, and the need for greater exactitude of knowledge.[51]

The present uncertainty regarding the natural mutation frequency carries with it a corresponding uncertainty regarding what proportion of the natural mutations in man are contributed by natural radiation. There is also uncertainty regarding this question based on variation in the amount of natural radiation. If we suppose that in some typical regions as much as 6 roentgens are accumulated, on the average, in the span of one human reproductive generation (25 to 30 years), then, on the more conservative estimate that the natural mutation frequency is equal to what would be induced by 37 roentgens, it turns out that some 16 percent of the natural mutations in man are produced by natural radiation. On the higher estimate for natural mutations, some 8 percent of them would be radiation-induced. In either case, the figure must be far higher than for short-lived organisms, such as mice or flies. On the other hand, in some

[51] Much of the information concerning mutation frequencies in Drosophila cited in the present report was derived from work by the present writer and his associates that had been supported by grants from the Atomic Energy Commission (contract AT (11–1)–195), the American Cancer Society (given on recommendation of the Committee on Growth of the National Research Council, United States of America), and the Rockefeller Foundation.

human populations living at a high altitude, with its greater cosmic ray intensity, the contribution of radiation to the natural mutation rate must be twice as high as here estimated. Still higher values must obtain for some populations living in regions where radioactive minerals are abundant.

Many persons unfamiliar with genetics have regarded the seeming normality of the children born to survivors of the Hiroshima and Nagasaki bombings as evidence against the conclusion that the amount of radiation there received produced a significant amount of genetic damage. This misunderstanding arises from their lack of realization of the following points.

1. Few mutations are sufficiently dominant to give readily perceptible effects when inherited from only one parent, as they are in the vast majority of cases.

2. Even though these effects are not perceptible they are nearly always sufficient to hamper the individual somewhat, and finally, usually in a very distant descendant, to cause the extinction of that line of descent.

3. In any heterogenously breeding population, such as is found anywhere outside of the geneticists' fields and laboratories, there is already so much natural genetic variation, representing an accumulation of many generations of natural mutations, that the additional mutations caused by the radiation would become lost to view among them even if they were as abundant as those that would arise naturally in the course of a number of generations. Thus, the genetically damaged population will eventually have to pay the costs, but these will be spread out over so many small installments, and so intermingled with the greater weight of other payments, as hardly to be recognizable. All this was of course well known to geneticists before the observations on the children at Hiroshima and Nagasaki were conducted, and led them to express serious doubts that any genetic effects would be demonstrable there, even though they had no doubts that they had actually been produced.[41]

These points may be better appreciated if it is realized that in *Drosophila* also it had not been possible to demonstrate the mutagenic action of radiation by mere inspection of the individuals of the first, second, or third generations after exposure. Exact genetic methods had first to be worked out[11] and these are of course unavailable in man. Even following an exposure of fly spermatozoa to some 5,000 roentgens, which we today know causes each offspring, on the average, to receive at least three induced mutations, hardly one abnormal offspring is usually to be found among 100 examined, yet the damage is there, and it will be exerted if the population is allowed to continue.

At the same time, it is true, unlike what many nongeneticists suppose, that the effects of the genetic damage are more strongly exerted in the first generation of offspring than in any subsequent generation. They very gradually subside, in the course of many generations, as the population is purged by the dying out of the unfit. Even the recessive effects, those present in individuals homozygous for the given mutations, are found most frequently in the first generation, and then less and less frequently if the population breeds naturally rather than being subjected to a geneticist's controlled inbreeding manipulations. Moreover, there is a much higher chance that a given induced mutation will become homozygous by meeting, at fertilization, a gene of the same type derived from the great accumulated store of natural mutations, than one of that type which, like itself, had been induced by the radiation.

Since the worst effects are already exerted in F_1, what the Hiroshima observations do demonstrate clearly is that the genetic damage to posterity caused by exposure to between one hundred and several hundred roentgens is not *conspicuously* detrimental, and is well within limits consistent with the survival and self-perpetuation of the population. This might have been reckoned as probable without the direct evidence. For, according to the conclusion that the average individual is already heterozygous for some 6, 8, or even more mutations which when homozygous would be fairly conspicuous and/or detrimental, it does not seem likely that the addition in heterozygous condition of just one more, induced by some 200 roentgens, would result in any very evident change in the picture. This remains true even when we take into consideration the fact that the already existing mutations have already passed, to varying extents, through the sieve of selection and are therefore not, on the average, as detrimental as the newly induced ones.

The apparent contradiction between the fact that a really serious amount of genetic damage was produced and the fact that none is evident even in the most

[41] See footnote, p. 1079.
[11] See footnote, p. 1072.

afflicted generation (the first), is reconciled by the manner in which the damage is spread out, thinner and thinner, over a great number of generations. There is a kind of buffering or dilution of the damaging effects, by the normal genes that dominate over them and thus delay their elimination. Thus the effects are spread out in time, in inverse proportion to their dilution in any one generation, but the total damage remains just as great as if concentrated. Moreover, even though the induced mutations may be many times the number that would arise naturally in one one generation, they are nevertheless few in relation to the accumulated natural "load." Hence they can raise by only a rather small percent the number of genetic shortcomings already present in the population.

Despite these buffering influences, it would be impossible for a population to tolerate, generation after generation, an exposure which, given to only one generation, would cause no perceptible deterioration. Gradually, as elimination rose enough to balance the new mutations, an equilibrium level of accumulation would be approached, and at this new level the then existing accumulated load would be as many times greater than the original accumulated load as the then existing mutation rate was greater than the original mutation rate. Thus, if 37 roentgens doubles the mutation rate, a population which had received this dose for many generations would at last have twice as many ills of genetic origin as we have. Yet we already have more than enough for comfort.

Not to be neglected in the picture is the other end of the balance mechanism; the rate at which elimination of mutations goes on. Under modern civilization we interfere so much with this that we are probably raising the load of accumulated mutations as fast as by applying some tens of roentgens to everyone's reproductive organs.[45] Under these circumstances the raising of mutation frequency at the same time, by exposure to radiation, might tend to bring us to a genetic situation that it would be difficult to cope with.

All these questions need to be not only discussed but actually investigated far more realistically than they have been in the past. Otherwise we may at last find ourselves, genetically, facing a parallel to already accomplished deforestation and erosion, on an even grander scale. This problem is not only one that is concerned with the possible aftermaths of atomic war. It must be faced equally by the proponents of peace if we are to have an atomic age, with its risks of prolonged "permissible" exposures arising from industrial uses and radioactive waste products.

For peace will, we hope, go on and on through a great series of generations. Under these circumstances, it will be the more necessary to control and limit the radiation received by the population at large in every generation. For, given enough generations, the equilibrium level of damage will be reached, at which that damage will no longer be buffered, but will accurately correspond with the existing mutation frequency. Then, a relatively small number of roentgens per generation will exert an inordinately larger effect than it seems to now. At our present juncture, before that process has more than begun, far-seeing policies should be established. These must guard us against the dangerous fallacy that what cannot be seen or felt need not be bothered with.

This subject of protection of human beings against the genetic damage produced by radiation must, until suitable policies are established, far overshadow in its importance that of the utilization of radiation in the genetic improvement, for human purposes, of organisms potentially useful to man, or in the elimination or reduction of noxious organisms. However, these constructive uses of radiation in biological engineering will come increasingly to the fore as the more menacing aspects of radiation are brought under control. There is already abundant evidence of the possibility of such beneficial applications on a considerable scale.[41, 53]

At the same time, the dangerous mistake should not be made of considering man as a species who would himself undergo a long-term benefit from the application of radiation to his germ plasm. His own reproductive material is his most invaluable, irretrievable possession. It is already subject to an amount of variation which, in relation to his present reproductive practices, borders on the excessive. Under these circumstances, man's first concern in dealing with radiation must be his own protection.

Representative HOLIFIELD. Are there any questions by members?

Representative VAN ZANDT. Dr. Muller, in regard to Russia, can you estimate the number of years it will take Russia to catch up with our progress in this field of radiation?

Dr. MULLER. I believe it will probably take them a long time. One would have to assess political factors there which are essentially unpredictable. Personalities play such a large role there, much larger than here, despite their theory of economic determination. Anyway, my estimate would be 10 or 15 years.

Representative HOLIFIELD. Thank you very much, Dr. Muller. Mr. Hollister wishes to ask you some questions.

Mr. HOLLISTER. Dr. Muller, I understand that you are familiar with the work of the Atomic Bomb Casualty Commission, and I wonder if you would comment on it and on the quality of and the conclusions from the data.

Dr. MULLER. I think it was evident to geneticists from the beginning that it was very doubtful whether any positive or essentially negative evidence could be obtained from a study of that kind, because human populations are so variable and it is so next to impossible to obtain two groups to compare, one irradiated and the other not, which are essentially similar in other respects. In view of that, I think that the present lack of results is not surprising even to most of those who took part in the investigation. I do not think they are to be blamed for it. There was some slight chance—because of the uncertainty of the estimates of the human mutation rate—that if the induced mutation rate was exceptionally high then some evidence of it could be obtained.

I think that it is very unfortunate to cite the lack of results from the study as indicating that there is no effect. I think that those reporting on the matter for the AEC in a December 1956 publication that I recently saw were quite right in saying that the data obtained there are not at all out of line with the expectation based on results with mice, that is, the frequency of induced mutations could well have been just as high among the human beings for the dose received as it would have been for mice, which is a matter we know a lot more about through Dr. Russell's experiments. We can go a little further than that and say that it could not have been a great many times higher than it is in mice, otherwise there would have been demonstrable results.

But we need not feel at all secure or relieved that no effects were found.

I remember that in a meeting of a committee called to decide whether these studies should continue one of the persons on the committee said, after I had remarked that I thought no effects would be found and that that would not prove anything, "That will be a very good thing because it will tend to allay the public fear on the matter."

Chairman DURHAM. Did you participate in writing the report?

Dr. MULLER. No; I did not. I may say this: I do disagree with a lot of the discussion in the last chapter where exception is taken to drawing conclusions from the results obtained in lower organisms. Certain criticisms are leveled against the work on flies and mice, for example, that I think are demonstrably unjustified and have a mistaken position. But that is not the major part of the work. When it

comes to the work on humans, I think that was done as well as could be expected under the very difficult circumstances.

Representative HOLIFIELD. Are there any further questions?

Representative VAN ZANDT. Dr. Muller, in the December 3, 1956, issue of the Federation of American Scientists you are quoted as saying this:

> It is reckless to increase the risk of war by continuing H-bomb tests. It is not the fallout from these tests that is at issue at this time but the war feeling. The first step for peace open to us is a discontinuance of tests by both sides. If breached by either side it can be detected by the other.

Will you comment on that statement?

Dr. MULLER. I was not speaking there primarily as a geneticist, but I think physicists are pretty generally agreed that the setting off of a test in the megaton range can be detected with certainty by the other side. So that a breach would be known and in that sense we already have 100-percent-effective inspection for tests of that kind.

Therefore, it is in that sense safe if both sides agree to discontinue the tests for them to act upon that agreement, since as soon as one side breaks it, the other side will know it.

Senator ANDERSON. As a matter of fact, Doctor, the first times that we detected tests we detected them with instruments that are primitive compared to what we now have; is that not true?

Dr. MULLER. And we detected ordinary atomic bomb tests of the other side.

Senator ANDERSON. So that a megaton test would be easily detectable, and there is no possibility of deception.

Dr. MULLER. Yes.

Representative HOLIFIELD. Thank you very much.

The next witness is Dr. W. L. Russell.

Dr. Russell comes from Oak Ridge, and has done important work at the Laboratory. We are glad to have you here and to have your statement.

STATEMENT OF DR. W. L. RUSSELL, OAK RIDGE NATIONAL LABORATORY [5]

Dr. RUSSELL. Mr. Chairman, members, the testimony to be given here is presented in response to one of the requests by this committee for scientific results on the biological effects of radiation caused by events other than fallout. Assuming the present estimates of radiation from fallout to be approximately correct, it would in fact be virtually impossible at the present time to measure the genetic effects of fallout in mammals. In estimating the genetic hazards of fallout, we are, therefore, forced into using the information obtained from experiments, such as those to be described, in which much higher levels of radiation were used.

[5] B. A., Oxford University, 1932; Sherman Pratt fellow, Amherst College, 1932–33; fellow, University of Chicago, 1933–34; asistant, department of zoology, University of Chicago, 1934–36; Ph. D., University of Chicago, 1937; research associate, Roscoe B. Jackson Memorial Laboratory, Bar Harbor, Maine, 1937–47; principal geneticist, Oak Ridge National Laboratory, 1947 to present; research and publications on the genetic effects of radiation in mice. In charge of the Mammalian Genetics and Development Section of the Biology Division of Oak Ridge National Laboratory. Member of the United States delegation to the 1955 Geneva Conference on the Peaceful Uses of Atomic Energy. Member of the Committee on Genetics Effects of Atomic Radiation, National Academy of Sciences. (Submitted by witness.)

The results described here were obtained from a series of experiments conducted in the Mammalian Genetics and Development Section of the Biology Division of the Oak Ridge National Laboratory. This program was started in 1947, the year the Atomic Energy Commission was founded. The preliminary work involved the construction of animal rooms and laboratories, the development and building up of special stocks of mice necessary for the experiments, and certain pilot experiments, including studies on the effects of radiation on fertility. The major experiments were started in 1949.

I was very happy that Dr. Sturtevant said what he did this morning about the lack of suppression of information and the desire to do good work in the national laboratories. I heartily concur, but such a statement comes more forcefully from a person outside the AEC, and one of Dr. Sturtevant's standing. I will say no more on this, other than that neither I nor any of my colleagues would attempt to do scientific work under conditions that were not free.

I think I might also add, and it would be ungrateful of me if I did not, that in addition to working under free conditions and not having our information suppressed, we have received personal encouragement, especially from the Division of Biology and Medicine of the AEC, including its Directors, from Dr. Warren, the first one, to the present one, Dr. Dunham.

Before the results of these experiments with mice were obtained, estimates of genetic hazards of radiation in man were based primarily on data from experiments with the fruitfly, *Drosophila*. Some information on the genetic effects of radiation in mammals was available, but most of this dealt with major chromosomal aberrations which are probably not an important hazard in human exposures. There was virtually no information on radiation-induced gene mutation rates in any mammal. The information now available from our experiments has therefore played a basic role in the new estimates of genetic radiation hazards made and published last year by the National Academy of Sciences committee in the United States and by the Medical Research Council committee in Great Britain. The United Nations Scientific Committee has also used this information.

In response to the request by this committee, I should like to present here a simplified up-to-date summary of our results, emphasizing the aspects which are useful in estimating human hazards. More detailed technical accounts have been submitted for the record to supplement this oral presentation. Again it must be kept in mind that these data were not obtained from fallout radiation. However, they can be used to estimate the genetic hazard from fallout, provided the radiation dose to the gonads is known. I shall describe two types of experiment. One of these measures the rates at which genes mutate by studying the effect of radiation on a particular selected sample of genes. The other measures damage in a population as a result of the total amount of mutation induced.

Most of our work up until recent times has been concerned with the former method, and so I shall describe the results obtained by it in more detail. The measurement of gene mutation rates is important, both for absolute and for comparative purposes. The particular method that we have used was chosen in the hope that it would be a fine-edged tool for making comparisons. One of these that was ob-

viously badly needed was a comparison of the mutation rates in any mammal with those in Drosophila. The mutation rate method chosen by us seemed likely to be the one which would give the most meaningful information on such a species comparison. Our present information on this point indicates that mouse genes are on the average approximately 15 times as sensitive to radiation as Drosophila genes. The earlier estimates of genetic hazards in man based on results in Drosophila have, therefore, been revised.

Another question on which information was badly needed was whether or not there is any recovery from genetic damage with time after irradiation. Some geneticists believed that there would be no such recovery. Others thought that some recovery might occur. Critical evidence on this point had not been obtained. Most of the information along these lines came from experiments with Drosophila sperm, whereas the evidence needed was for immature sex cells. Let me elaborate for a moment on the importance of the cell stage, i. e., immature versus mature germ cells, before we continue with the question of recovery.

In the testis, the immature germ cells—called spermatogonia—persist throughout life. Cells are constantly budded off from them and, after further multiplication, develop into the mature sperm cells. The time required for the development of a mature sperm from an immature spermatogonium is only a few weeks. When we are exposed to continuous or intermittent radiation, the dose received by a cell up to and including the spermatogonium stage is the total dose received over the whole period from conception of the individual up to the time when the spermatogonium starts its final development. This is obviously going to be much greater than the dose received during the few weeks of its final development into a sperm cell. Even with acute radiation received as a single dose, the chance of a fertile mating occurring within a few weeks after exposure is small compared with fertile matings that will occur at later intervals. Thus again it is usually the dose received by the immature cells which will count. Therefore, the problem of genetic hazard of radiation in man relates primarily to the immature germ cells. It is on these cells that our studies of induced mutations in mice have been conducted. This has many important implications, one of which is on the question of recovery, to which we can now return.

How might the question of cell stage affect recovery following irradiation? It is possible to imagine that an immature germ cell in which a mutation has been induced might multiply at a slower rate than a normal cell. This is one example of a possible mechanism by which some recovery from genetic damage might occur. It is obvious that experimental data from mature germ cells in Drosophila could not answer such a problem. Considering the possibility that I have just mentioned, along with others, it was clear to us that the question of recovery with time had to be investigated for immature germ cells. It also seemed important that the problem be examined in an organism with a generation time much longer than that of the fruitfly, which is only 10 days, and in mammalian gonads, which are quite different in their makeup and function from those of insects. Having now obtained this information, we find that in spite of the possible mechanisms by which recovery might have occurred, there

is in fact no evidence of any significant recovery with time after irradiation. The offspring of a mating made a long time after irradiation is just as likely to contain a gene mutation as is the offspring of a mating made shortly after irradiation. I might interject here that I am talking only about irradiated spermatogonia. If we included the sperm, there would be some recovery within a short time after radiation. In human hazards, however, we are concerned, as I have already explained, primarily with the immature germ cells. Thus it would appear that it is the cumulative dose which is important, and this principle is now established for the immature germ cells of a mammal. I have dwelt on this point at some length because I have found it to be one that is often raised in discussion. We are so used to the body being able to recover from various types of damage that it is quite reasonable to require rigorous proof that this does not occur with genetic damage.

Another problem that was investigated by our method for measuring gene mutation rates is the relation between mutation rate and dose. On the basis of experiments with other organisms, a linear relation was expected. In other words, it was expected that mutation rate would be directly proportional to dose, that, for example, doubling the dose would double the mutation rate.

Dr. Crow this morning assumed this principle and stated that he was basing his assumption on Drosophila. Therefore, I think it appropriate to state what information we have in this respect in the mouse.

Our first data came from males exposed to 600 roentgens. As the data started to come in from males exposed to 1,000 roentgens it became clear that the mutation rate was significantly lower than expected on the basis of the 600 roentgen results. It seemed likely that this result, which was unexpected on the basis of Drosophila results obtained up to that time, might be due to the fact, already emphasized, that we were dealing with immature germ cells (spermatogonia) in the mice, whereas Drosophila results had been obtained from mature germ cells. If, for example, there were differences in sensitivity to mutation induction correlated with sensitivity to killing of the cells, then at the higher doses the mutation rate observed might represent only the mutation rate for the surviving and more resistant cells. Careful studies in our laboratory by Dr. Oakberg on the amount of killing of spermatogonia with various doses of radiation support this possibility.

Whatever the explanation might be, it was clear that it was important to obtain data on mutation rates at doses lower than 600 roentgens. Since the relation between mutation rate and dose has been found not to be directly proportional above 600 roentgens, it was possible that it would also not be proportional below 600 roentgens. We have therefore begun experiements at lower doses. The data so far obtained from a 300-roentgen experiment show no significant departures from proportionality with the 600-roentgen results. More data are, however, needed.

Representative Holifield. At that point, Dr. Russell, could you tell this committee how near you think the experiments on mice would correspond to the radiation of human beings? You have made the statement that the mouse is 15 times more sensitive than the fruitfly. Can you give us a comparison between the mice and the human being?

Dr. RUSSELL. I have prepared a short statement involving the whole problem of extrapolating.

Representative HOLIFIELD. Is that contained in the statement?

Dr. RUSSELL. It is not in the typed copy you have, but I shall be glad to read it.

Representative HOLIFIELD. Or could you give me a summary right now?

Dr. RUSSELL. I believe a summary is the best we can do at the present time. I might explain a little more about this dose relation, if I may, on the board.

If we put the 600-roentgen mutation rate at this point here, the 1,000-roentgen result instead of being up here, as expected from the linear relation found in Drosophila, turned out to be down here [pointing on blackboard].

Representative COLE. Doctor, would you go back to the microphone and repeat what you said, because I do not understand it.

Dr. RUSSELL. The first result we got was with the 600-roentgen experiment and is shown here. The points immediately above and below it that I have connected with the line represent the 95-percent confidence interval for this result, that it, with 95 percent probability the true value should lie within that range. The 1,000-roentgen result was expected, from the linearity found in Drosophila experiments, to be correspondingly higher than the 600-roentgen, but actually came out lower. In other words, the relation is not linear. This raises the question of why there is linearity in Drosophila and not in the mouse.

As I have said, we felt that perhaps this lack of linearity in the mouse was due to the killing of the spermatogonial cells themselves, and that at the higher dose the result represents the mutation rate of more resistant cells which were not killed. At the lower dose you get a mutation rate for more sensitive cells, some of which have not been killed.

The question arises what is the curve going to do below 600 roentgens? You can no longer predict that it will be linear between 600 roentgens and zero. There is now some likelihood that it will be higher than expected on a linear basis. Up to this time in the hearings we have had a good deal of discussion of whether the mutation rate is linear and if whether some somatic effects are linear or whether they go up this way, that is, concave upward. These mouse mutation results represent something going this way, that is, convex upward. In other words, the effect at lower doses might be higher than expected on a linear basis. It was obviously important to obtain data at the lower doses. The 300-roentgen result looks like this. At the present time it falls close to the straight line drawn between the results for the 600 roentgens and the zero doses, but as I say, I think we need more data on this point.

Representative HOLIFIELD. This would indicate, then, if this theory becomes established, that the lower dose rates would cause more mutations in the germ cells than the higher rate.

Dr. RUSSELL. This is a possibility raised by this departure from linearity at high doses.

Representative HOLIFIELD. That is because the higher dose kills the cell.

Dr. RUSSELL. That is right. The amount of killing of cells is quite high so it is still possible to get some departure from linearity at lower doses. So we feel that this point needs further experimentation.

Representative HOLIFIELD. But you are not yet ready to set the rate?

Dr. RUSSELL. Three hundred roentgens was the first attempt to provide some information between 600 roentgens and zero. As we go down in the dose, it is much harder to obtain the data because fewer mutations are obtained.

Chairman DURHAM. Are you using only flies?

Dr. RUSSELL. This is all on mice.

I might also interject at this point another comment. A good deal has been said about there being no Drosophila data on mutation rates below 25 roentgens and about there being no mouse data below 300 roentgens. Yet, again referring to Dr. Oakberg's work in our laboratory, he can see and actually measure the killing of spermatogonial cells with doses as low as 2 or 3 roentgens, and even with 1 rep of neutrons. A dose of 22 roentgens kills half of the sensitive spermatogonia. So it seems to me that if we can actually see cells that have been killed by doses as low as 2 or 3 roentgens, and can put this on a quantitative basis, if cells are actually killed at these dose levels, there is no question in my mind that there will be genetic effects from doses as low as this.

Representative HOLIFIELD. This has a tremendous impact on the theory of threshold, does it not?

Dr. RUSSELL. It certainly helps to answer the question of threshold for genetic effects. Of course, the question of threshold for some somatic effects is not answered by this, because killed cells might be replaced by normal cells. So it does not conclusively prove anything about the question of a threshold for somatic effects. I think it supports the already quite well established point of there being no threshold for genetic effects, because here is direct experimental evidence on mammals that cells can be killed measurably by doses as low as 2 or 3 roentgens.

Representative HOLIFIELD. You have been able to observe those?

Dr. RUSSELL. The killed ones can be observed, yes.

Another comparative study that can be made with the gene mutation rate method used by us is on the variation in mutation rates of different genes. Extensive information on seven different genes in the mouse shows a wide range in their mutation rates. The difference between the lowest and the highest rates is more than thirtyfold. This finding is of interest in many respects. For example, it raises the possibility that the so-called rate-doubling dose, the dose required to double the spontaneous rate, might be quite different for different genes.

The results from our gene mutation rate method that I have so far described have been useful primarily for comparative purposes. Thus we have been able to compare mutation rates in mice and fruitflies; we have been able to compare mutation rates at short and long intervals after irradiation; we have compared mutation rates at different doses; and so on. Additional work now going on with this method will, in addition to measuring mutation rates at lower doses, also give information on other comparisons—for example, a comparison between the mutation rates in females and males, a comparison of the

results from long-continued low-level irradiation with those from single dose acute radiation, and so on.

Although designed primarily to provide information for the comparisons that I have already described, the gene mutation study has given some information on the nature and amount of total damage to be expected. First with regard to the nature of the damage, considerably more than one-half of all the radiation-induced mutations obtained from the seven genes studied in detail have proved to be recessive lethals—that is, when an offspring inherits the mutation from both parents, it will die. It seems unlikely that this result is biased in the unfavorable direction, because before the experiments were started it was not known whether or not any of the seven genes chosen for the study could mutate to lethals.

Representative HOLIFIELD. Will you explain that term "recessive lethal"?

Dr. RUSSELL. That is when an offspring inherits the mutation from both parents, it will die. When the organism inherits it from one parent, it won't die. It seems unlikely that this result is biased in the unfavorable direction, because before the experiments were started it was not known whether or not any of the seven genes chosen for the study could mutate to lethals. In other words, the sample of genes chosen was not chosen for production of this type of mutation at all. It was not known whether they could even mutate to lethals.

Some information has been obtained on the time at which these lethals kill the individuals who inherit them from both parents. All the lethals that have occurred at one gene locus kill the offspring at about weaning age. The lethals obtained from another gene locus apparently vary considerably in their time of killing. More information is needed on this point, but it is already clear that a large proportion of the lethals already studied kill at times that would be considered tragedies in human experience. Most of the lethals found do not belong to the category of lethals in which death occurs so early in development of the embryo as to pass unnoticed.

It was anticipated that some, perhaps most, of these lethals would have some deleterious effect when inherited from only one parent. Such deleterious effects have already been observed for some of the lethals. It was expected that these deleterious effects might be observable only in a statistical sense in populations. However, in some cases the deleterious effect of a lethal when inherited from only one parent is large enough to be detectable in the individual. It should be mentioned that a lethal which has a deleterious effect when inherited from only one parent will express its damage in the population far more frequently in this way than in the more drastic effect that occurs when it is inherited from both parents.

As has been mentioned, the results of the gene mutation study can be used to estimate total mutation rate. One way of doing this is to take the information from Drosophila on the ratio of total mutation rate to mutation rate at specific genes and use this to make the calculation of total rate on the basis of mutation rates at specific genes in the mouse. This method of estimation was used in the report of the Genetics Committee of the National Academy of Sciences. Dr. Muller used it before, and I think Dr. Crow incorporated this idea in his calculation this morning.

More direct methods of measuring the overall genetic damage are desirable and one of these is the second of the two methods I should like to describe in this testimony. This method was suggested by the evidence that had begun to accumulate that there are slight dominant deleterious effects of mutations formerly regarded as recessive. Two lines of such evidence came from our work on mice. One has already been mentioned, namely, that at least some of the recessive lethals obtained have some dominant effects. The second line of evidence came from the large populations of animals examined for gene mutations. In that study, the offspring were kept to 3 weeks of age, and it was found that survival to this age was slightly lower in the offspring of irradiated males than in the controls. As a result of these findings, and of evidence from other organisms, it began to seem probable that other effects might be detectable in the first generation offspring of irradiated mice. Shortening of life was chosen as an effect that might reveal, as a statistic of a population, the presence of a variety of minor weaknesses which individually could not be easily detected. Pilot studies on longevity in the descendants of irradiated mice were accordingly started. The results from the first of these were presented before the National Academy of Sciences a few weeks ago, and have just been published.

Dr. Crow did not discuss these this morning. I asked him whether be did not believe them. He said "No," he had left them for me to discuss, and I think he felt it was more appropriate as they are quite recent data.

Representative COLE. When you say that he responded to the question of whether he believed them or not, by saying "No," did he mean he did not believe them, or that was not the reason?

Dr. RUSSELL. That was not the reason.

Senator ANDERSON. Are you going to discuss them?

Dr. RUSSELL. I have submitted for the record the detailed account of this which has been published. I shall be glad to read from this or cite any parts.

Senator ANDERSON. You were here the other day when I read briefly from the news story.

Dr. RUSSELL. Yes.

Senator ANDERSON. Is that what it is based on?

Dr. RUSSELL. Yes.

Senator ANDERSON (reading):

> Neutron radiation from atomic bomb can shorten the life of a man's children.

This is quoting from you.

> Offspring from a man exposed to such radiation will have their lives shortened on the average of 20 days for each unit of radiation their father has received.

Dr. RUSSELL. Yes.

Senator ANDERSON. We have been talking about receiving up to 400 roentgens. We multiplied that out and came to 8,000 days, and that was 22 years.

Dr. RUSSELL. There are two major qualifications which I believe were included in some of the news reports. I remember that they were in the full Science Service report. These qualifications are first, that we were dealing with neutrons which are probably more effective than X-ray or gamma rays. The other is that we were not dealing with the spermatogonia. In this experiment we deliberately tried to

maximize everything to get the effect on scale so that if there were any such effect, we would detect it. In this we used the maturing germ cells which for mutation rates are at least, shall we say, 2 to 4 times as sensitive as the spermatogonia for straight gene mutation rates. It is possible they are even more sensitive for this effect, but this we don't know yet. A more conservative conclusion from the results is the one I put in the discussion. I think at the present time we would be justified in estimating the effect on the first generation of offspring to be between one-tenth and equal to the effect on the shortening of life of the exposed individuals.

I think it is perhaps fairer to talk about this than the 20 days which, in several respects, is maximized.

Senator ANDERSON. I know. Apparently this article in the Science Service was quoting you. It said, "Dr. Russell found, however, that 'There was a significant effect of radiation on the length of life of the offspring.' In the male mice"—I am sorry, the quotation marks were dropped there. It says the life of the offspring was shortened 0.61 days, I assume, for each unit of radiation.

Dr. RUSSELL. Yes.

Senator ANDERSON. Does that refer to mice?

Dr. RUSSELL. Yes; that refers to mice. A unit of radiation in this case was the rep of neutrons rather than the r. for X-rays or gamma rays. There should be some reduction factor. This is not known. But perhaps it is a factor of about 2.

Senator ANDERSON. Quoting further from this article—

> Using this information for human beings, Dr. Russell has figured out that a man's life will be shortened from 5 to 35 days for each unit of radiation received by the father.

Is that a correct statement?

Dr. RUSSELL. That is correct. This again refers to the conditions of this experiment, which are not the conditions of human exposure.

Representative PRICE. What was the unit of radiation?

Dr. RUSSELL. The unit of radiation was a rep.

Representative COLE. A rep is what fraction of a roentgen?

Dr. RUSSELL. A rep is equivalent to the roentgen in its physical effect on tissue, but is more effective in its biological effect for most types of biological effect.

Representative HOLIFIELD. Are you drawing the line between the neutrons which would be received close to a bomb explosion, and the gamma and other types of rays that would be received far away?

Dr. RUSSELL. That is partly correct. There would be a mixture of neutrons and gamma rays. Our experiment was set up only to measure the neutron effects. The animals were shielded behind lead to filter out the gamma radiation. The experiment, as I emphasized in the paper, was not conducted primarily for this particular study. We got the data which showed this rather striking effect, so reported it. We are now conducting experiments designed deliberately to measure the shortening of life. But we felt we should not wait for the completion of these before reporting the effect already observed. However, the qualifications are important, and I must insist that they be understood. Otherwise if you just take the 20-day figure and do not put the qualifications on it, it is probably a much larger effect than would be obtained under normal conditions of human exposure.

Senator ANDERSON. It says—

This shortening of life in the immediate offspring, Dr. Russell warns, in the Proceedings of the National Academy of Sciences, will turn out to be of a magnitude that will warrant serious consideration as a genetic hazard in man.

Is that a correct quotation?

Dr. RUSSELL. That is a correct quotation. I have the same statement in this testimony I was about to read. I do believe that, in spite of the qualifications, this is still a serious effect. I think the 20-day figure is too high. For conditions of human exposure, at least by our present estimates, it should be somewhat lower, but I still think it would be serious.

Senator ANDERSON. From 5 to 35 is a safe figure.

Dr. RUSSELL. No; that would still be under these conditions. If you want a definite figure, I would say at the present time something more like 1 to 10. These are guesses. It is much safer to publish the data you have and put the qualifications on them, than to make guesses about the quantitative values of the qualifications.

Senator ANDERSON. It was pointed out that it could take up to 10 and with 400 r, that would produce 4,000 days which would be 11 years, which would be quite a shortening of human life.

Dr. RUSSELL. Yes.

Senator ANDERSON. Which would be serious.

Dr. RUSSELL. Yes, 400 r. would be serious. To conclude the statement on this, some of which we have already discussed: Our data on this effect are not yet as extensive as we should like. However, though the first sample studied was small, it was sufficient to yield a statistically significant effect which appears to be large and, therefore, of general importance. It should be kept in mind that some of the conditions of this experiment were set up deliberately to increase the chance of obtaining a detectable effect. However, since the effect observed appears to be so large, it seems likely that, even when allowance is made for the conditions of human radiation exposure, shortening of life in the immediate descendants will turn out to be of a magnitude that will warrant serious consideration as a genetic hazard in man.

In conclusion, I should like to emphasize one point in addition to those already expressed in this presentation, a point that Dr. Crow mentioned this morning. The layman tends to think of mutations in dramatic terms as gross monstrosities occurring in the first generation following radiation. Our studies on mice confirm the results obtained from other organisms showing that these are exceedingly rare types of genetic damage. Mutations which cause slight deleterious effects are far commoner.

Before summarizing these points, I should like to say a word or two about extrapolation from mouse to man, the question which the chairman raised earlier. There are, of course, risks in this. I think some of the earlier testimony, from medical workers and others, overemphasized the difficulty. Yet, applying animal results to man is exactly what is done all the time in medicine in the testing of drugs and so on. Others who objected to the extrapolation of mouse mutation data to man had no qualms about extrapolating the rate-doubling dose. I personally would feel safer about extrapolating the induced mutation

rate in mammals from mouse to man than about extrapolating the rate-doubling dose itself.

I will certainly agree that there are some risks in extrapolating on the quantitative points, that is, the actual mutation rates. I think the risks are very much less in extrapolating with regard to the principles or relations between various points. Such principles as the lack of recovery with time, the shape of the dose curve, the relative frequencies of different types of mutations and so on, it seems to me, can be extrapolated with fair confidence.

Some of these are principles that cannot be extrapolated from fruit-flies, because of the biological difference between flies and mammals. Other principles, of course, which were very well established in flies can be extrapolated to mammals. I have been stressing in this report those which I think needed work directly on mammals.

I have listed nine points of this testimony in summary.

1. Present data indicate that mouse genes are approximately 15 times as sensitive to the induction of mutation by radiation as fruit-fly (*Drosophila*) genes.

2. There is no recovery from genetic damage with time after irradiation. This principle has now been established by direct experimental evidence on the material in which investigation was badly needed, namely, the immature germ cells of a mammal.

3. Mutation rates following a dose of 1,000 r. show a significant departure from proportionality with the rates obtained at lower doses. Mutation rates at 300 r. and 600 r. do not as yet show any significant difference from proportionality. However, more data are needed, especially in view of the observed departure from proportionality at the higher dose.

4. Different genes show widely different radiation induced mutation rates.

5. More than one half of the radiation-induced mutations obtained have proved to be recessive lethals—that is, when an individual inherits the mutation from both parents it will die.

6. Most of these lethals do not belong to the category in which death occurs so early in development of the embryo as to pass unnoticed. On the contrary, they kill at times that would be considered tragedies in human experience.

7. The deleterious effect of some lethals when inherited from only one parent is large enough to be detectable in the individual.

8. Rough estimates of the total mutation rate expected from a given dose of radiation have been made from the sample of mouse genes studied.

9. More direct methods of measuring overall genetic damage are being used. The first results from one of these show a significant shortening of life in the first generation offspring of irradiated male mice.

In presenting this statement today, I hope I have given the committee a useful picture of at least a part of the basis on which conclusions on the genetic hazards in man have been reached. Thank you.

Representative HOLIFIELD. Thank you very much, Dr. Russell. I think you have given a very important statement here. It certainly seems to prove that in the case of genetics, at least, any radiation is harmful to the genes.

Are there any questions?

Representative COLE. Mr. Chairman, I do not recall that the doctor responded to your inquiry with respect to the relative sensitivity of human cells in comparison with mice.

Dr. RUSSELL. I think there is some question about extrapolating the exact mutation rate from mice to man. I think there is less risk in extrapolating the principles that we have established in our experiments. However, I think the best we can do at the present time is to use the organism closest to man on which we have data, and that is the mouse. I personally would feel less worried about extrapolating the induced mutation rate from mouse to man than I would about some other extrapolations that have been made.

Representative COLE. Then you are unable to give us any estimate of the ratio between fruitfly, mice, and human being?

Dr. RUSSELL. We have the ratio between mouse and fruitfly. This is 15 to 1. With regard to man and mouse, we have no information other than such as has been discussed. It appears from the Hiroshima and Nagasaki data that man is probably not greatly more sensitive than the mouse. Otherwise more damage would have been observed. However, the results on the Japanese study are fully consistent with a rate as high as has been found in the mouse. I would, like Dr. Muller, quarrel with some of the final conclusions of the report on the study in Japan. I would quarrel with one statement there about this particular point. Even so, in the report on this study, the authors do not raise any question about man being less sensitive than the mouse to radiation-induced mutation. I think the data are not extensive enough to rule out the possibility that he could be more sensitive than the mouse.

Chairman DURHAM. Your second summary point you base on how many years of research, that is, there is no recovery from genetic damage?

Dr. Russell. The first indication came after, I would say, about 2 years' work after the basic experiments were started. This has been further confirmed by more extensive data as time has gone on.

Representative HOLIFIELD. This refers to your experiments on mice.

Dr. RUSSELL. Yes.

Representative HOLIFIELD. Thank you very much, Dr. Russell. We will place your article, Shortening of Life in the Offspring of Male Mice Exposed to Neutron Radiation From an Atomic Bomb, in the record at this point.

(The material referred to follows:)

[Reprinted from the Proceedings of the National Academy of Sciences, vol. 43, No. 4, pp. 324–329, April 1957]

SHORTENING OF LIFE IN THE OFFSPRING OF MALE MICE EXPOSED TO NEUTRON RADIATION FROM AN ATOMIC BOMB[1]

By W. L. Russell, Biology Division, Oak Ridge National Laboratory, Oak Ridge, Tenn.

Communicated by Sewall Wright, January 31, 1957

Introduction.—Only in recent years has evidence begun to accumulate that there are slight dominant deleterious effects of mutations formerly regarded as

[1] Work performed under Contract No. W-7405-Eng-26 for the United States Atomic Energy Commission.

recessive.[2-5] The results to be reported here, and our earlier work on mice,[4, 6, 7] indicate that such effects may add up to an important part, perhaps the most important part, of the genetic hazards of radiation in man. The evidence from the earlier work on mice is that appreciable deleterious effects of radiation become manifest in the first-generation offspring. This evidence is of two kinds. First, work on radiation-induced mutations at specific loci in spermatogonia has shown that among the recessive lethals, which comprise more than one-half of all the mutations recovered, many have dominant deleterious effects which, even for individual mutations, are sometimes large enough to be detected easily. Second, overall population damage was found in the large numbers of animals that are raised as far as 3 weeks of age in the specific loci studies. In all such experiments carried out, the survival to 3 weeks of age is significantly lower in the offspring of irradiated males than it is in the controls. (It should perhaps be pointed out that neither of the above effects, nor the effect reported in this paper, is the result of what the geneticist usually refers to as "dominant lethals," which are major chomosomal aberrations that cause early death of embryos and which, as has been pointed out elsewhere,[6] are probably not an important hazard.)

Our earlier work that showed a significant effect on survival to 3 weeks of age in the offspring of irradiated males led us to expect that there would be measurable deleterious effects later in life. The data reported here show that such is indeed the case. These data furnish a third kind of evidence of first-generation damage and perhaps the most striking one. They were obtained as a byproduct of another investigation, and they are not as extensive as we should like. However, they are the only data we have on this subject that were collected under the expensive and difficult conditions of a field test of a nuclear detonation. Furthermore, although the sample was small, it was sufficient to yield a statistically significant effect which appears to be large and, therefore, of general importance.

Materials and methods.—The material used in the present longevity study was the byproduct of an investigation of the relative effectiveness of neutrons from a nuclear detonation and from a cyclotron in inducing dominant lethals in the mouse.[8] In order to reduce the gamma component of the radiation to a proportion that would not appreciably interfere with the estimation of neutron effects, the animals were shielded with lead. The exposure chambers available were lead hemispheres of 7-inch wall thickness and 14-inch inside diameter. Young adult hybrid males, obtained by crossing inbred 101 strain females with inbred C3H strain males, were exposed inside the hemispheres placed at various distances from the detonation. Control males were placed in hemispheres 2 days before the detonation and for a length of time approximately the same as that required for the exposed animals. Further experimental details are described in the report of the earlier work.[8] One day and a half after the detonation, each male was placed with four adult untreated females of the same hybrid strain. At 18½ days after irradiation each surviving male was placed with a new group of 4 females. Most of the females that became pregnant were killed at a late stage of gestation for the dominant-lethal study. However, since the number of pregnancies turned out to be more than adequate for the dominant-lethal experiment, several of the females were allowed to come to term. It was the offspring of some of these females that were saved for the longevity study described here. All these animals came from matings made from 19 to 23 days after irradiation. A few animals died before weaning, and these were not included in the data reported here. At weaning age the sexes were separated and the animals grouped, so far as possible, six to a cage. They were kept in the same grouping throughout their life span. They were checked at least twice weekly for deaths. Only one animal died at less than 1 year of age, indicating that the conditions under which the animals were kept were good.

The total (neutron plus gamma radiation) dose inside each lead hemisphere was measured, as described in the earlier publication,[8] by means of tissue-

equivalent ion chambers designed for this purpose at short notice.[9] Subsequently, extensive testing and recalibration of these chambers[10] has led to a revision of the original dose estimates. The doses reported in the present publication are the revised estimates. As was reported earlier,[8] attempts to measure the gamma component of the radiation by means of film dosimeters left a large uncertainty as to the size of this factor. Later tests have been made in which both ionization chambers and chemical dosimeters were used to measure the gamma component inside the lead hemispheres when these were exposed to fission neutrons. According to the latest information,[11] these tests indicate that the gamma-radiation exposure in our experiment was almost certainly less than 10 percent of the total dose.

Results.—The median and mean lengths of life, together with the number of animals, for each dose group are given in table 1. An analysis of variance showed that neither grouping in cages nor sex had a significant effect on length of life. It seems likely that larger samples would show some effect of both of these factors, but as there was no significant effect of them in the present experiment, the data were pooled.

TABLE 1.—*Length of life in the offspring of male mice exposed to neutron radiation 19–23 days before mating (deaths before weaning age excluded)*

Total dose to parent (rep) [1]	Number of offspring	Median length of life of offspring (days)	Mean length of life of offspring (days)
0	103	823	792
31	50	741	754
71	5	717	699
118	22	739	723
136	8	666	688
186	2	756	756

[1] Includes some gamma radiation, estimated to be less than 10 percent of the total dose.

To test whether there was a significant effect of radiation on the length of life of the offspring, the means were fitted to a straight line by the method of weighted least squares. This gives an intercept of 786 days and a slope of -0.609 ± 0.238. Since the residual variance is less than the within-subclass mean square, there is no evidence of nonlinearity over the dose range tested. Even if the true shape of the curve is nonlinear, it will be conservative, in making the test of significance, to assume linearity. The larger mean square was used to compute the variance of the slope, and a two-sided t-test shows that the slope differs significantly from zero at the 1-percent level. If one is willing to accept a one-sided t-test as more appropriate, the significance level is 0.5 percent. Thus there is strong evidence of shortening of life in the offspring of the exposed males.

Discussion.—It is noteworthy that a significant shortening of life was detected in spite of the small sample and the considerable genetic variability that must have been present in a population that was the F_2 of a cross between inbred strains. Furthermore, the weighted mean dose received by the exposed fathers was only moderate, being less than one-sixth of the 30-day median lethal dose as measured from other animals of the same strain exposed under the same conditions at distances closer to the same detonation. While it is true that certain features of the experiment, which will be discussed later, tended to maximize the shortening of life, nevertheless the result observed appears to be so large that it seems quite possible that shortening of life is an effect that might be detectable in studies of the offspring of exposed parents in human populations.

TABLE 2.—*Shortening of life in the offspring of fathers exposed to neutron radiation 19 to 23 days before mating—Observed result in the mouse and extrapolation to man (deaths before weaning age excluded)*

	Mouse	Man
Point estimate	0.61 day/r. e. p. to father	20 days/r. e. p. to father.
Lower 95-percent confidence limit	0.14 day/r. e. p. to father	5 days/r. e. p. to father.
Upper 95-percent confidence limit	1.07 days/r. e. p. to father	35 days/r. e. p. to father.

In view of the lack of information on this subject, and specifically the fact that no data of this nature were ready for consideration prior to the writing of the 1956 report of the National Academy of Sciences Committee on Genetic Effects,[12] it is desirable to consider what the present data might indicate when they are extrapolated to man. Taking the estimate obtained from the curve fitted to the mouse data, and assuming that the shortening of life in man would be proportional to this, gives, on the basis of a 70-year length of life in man, the figures shown in table 2. It should be kept in mind that the results were obtained from neutron irradiation. The relative biological effectiveness of neutrons for this effect is not known, but it seems likely, from other data on mutations, that gamma and X-radiation would be less effective than neutrons. It should also be emphasized that the effect observed here is probably a maximum one, since the offspring were obtained from matings made between 19 and 23 days after irradiation. Our data from experiments on mutations at specific loci [13] indicate that the sperm utilized in matings made within this time interval would have been derived from cells in a sensitive stage of gametogenesis at the time of irradiation. From approximately 2 to 4 times as many mutations are recovered from this stage as from the spermatogonial stage, which is the important one so far as radiation hazards in man are concerned.[6] It is also possible that the spectrum of mutations from irradiated spermatogonia would be qualitatively different and, conceivably, less effective in shortening life. However, there is no direct evidence of this, whereas there is evidence from our specific loci studies that some mutations induced in spermatogonia have, even individually, a dominant effect on length of life that is detectable. To summarize this paragraph, it should be remembered that the estimates given in table 2 are based on neutron irradiation of a postspermatogonial and sensitive stage in gametogenesis and that X- or gamma irradiation of spermatogonia would almost certainly produce a smaller effect.

Another way of considering the magnitude of the observed results, so far as its human implications are concerned, is to compare the shortening of life in the offspring of irradiated fathers with that in the irradiated individuals themselves. The data on shortening of life of the males exposed to this same detonation will be presented in detail elsewhere. Briefly, the percentage shortening of life of these animals, based on 24 controls and 128 exposed animals, is 0.078 percent per r. e. p.

The present data, expressed in the same form, give 0.077 percent shortening of life in the offspring for each r. e. p. received by the father; that is, approximately as much effect as on the exposed individuals. Thus the best estimate from our present data is that, for neutron irradiation of the sensitive stages in spermatogenesis, the shortening of life in the offspring of irradiated males will be similar in magnitude to that in the exposed individuals. Again, the effect from irradiation of spermatogonial stages would probably be less. Whether the *ratio* of effect in offspring to effect in exposed individuals will be different for X- and gamma rays from that observed for neutrons will, of course, depend on whether the relative biological effectiveness of neutrons is different for the effect on the offspring and the effect on the exposed individuals. Present, incomplete data on these points give no grounds for expecting that the ratio of effect in offspring to effect in exposed individuals will be less for X-rays than for neutrons. Weighing the evidence reported here, and making

[13] W. L. Russell, USAEC Unclassified Report ORNL-2155 (Washington; Office of Technical Services, Department of Commerce, 1956).

some allowance for the many uncertainties, it seems reasonable to predict that, even under the conditions of radiation exposure in man, shortening of life in the offspring of irradiated fathers will be between 10 and 100 percent of the shortening of life in the exposed individuals themselves. It should be remembered that this excludes an additional effect on the offspring; namely as measured in the mouse, death before weaning age. Also, and more important, since the shortening of life is probably the result of mutations with slight dominant effects, the damage would not end with the first-generation offspring but would, to a certain, and probably large, degree, be transmitted to later generations.

Summary.—Length of life in the offspring of male mice exposed to moderate doses of neutron radiation from a nuclear detonation is shortened by 0.61 day for each r. e. p. received by the father over the dose range tested. This figure excludes death before weaning age. The 95-percent confidence limits are 0.14 and 1.07 days per r. e. p. Extrapolating to a proportional shortening of life in man gives 20 days per r. e. p.received by the father as the point estimate and 5 and 35 days as the 95-percent confidence limits. The offspring were obtained from matings made from 19 to 23 days after irradiation and, therefore, represent the effect of irradiation on germ cells in a postpermatogonial and sensitive stage of gametogenesis. It is probable that irradiation of spermatogonia (the stage that is important from the point of view of human hazards) would give a somewhat smaller effect. However, since the present data show an effect on the offspring which is as large as the shortening of life in the exposed individuals themselves, it seems likely that, even when allowance is made for the conditions of human radiation exposure, shortening of life in the immediate descendants will turn out to be of a magnitude that will warrant serious consideration as a genetic hazard in man.

The author gratefully acknowledges the cooperation of Mr. R. L. Corsbie, Dr. E. P. Cronkite, Dr. H. H. Plough, Dr. R. E. Carter, Dr. E. F. Oakberg, Dr. C. W. Sheppard, and Dr. V. P. Bond, all of whom gave valuable assistance in various phases of the work at the test site. The author is also indebted to Dr. A. W. Kimball for statistical advice and computations and to Mrs. Josephine S. Gower and the other members of the Mammalian Genetics and Development Section who assisted with the laboratory work.

Representative HOLIFIELD. Before we have our discussion, we are going to ask Dr. Hardin Jones, to give his presentation.

STATEMENT OF DR. HARDIN JONES, UNIVERSITY OF CALIFORNIA RADIATION LABORATORY[a]

Dr. JONES. Thank you.

Representative HOLIFIELD. Dr. Jones, this is your prepared statement?

Dr. JONES. Yes.

Representative HOLIFIELD. It will be accepted for the record. Are you going to summarize it?

Dr. JONES. Yes.

(The statement referred to follows:)

STATEMENT OF HARDIN B. JONES, PROFESSOR OF MEDICAL PHYSICS, PHYSIOLOGY; ASSISTANT DIRECTOR, DONNER LABORATORY, UNIVERSITY OF CALIFORNIA

My field is the physiological basis of human health problems. In research I have contributed appreciably to: (1) an understanding of some metabolic disturbances associated with heart and vascular disease; (2) evaluations of the

cancer problem and especially human cancer therapy; (3) the study of aging in that I have been able to construct a general explanation of aging that can be subjected to experimental study and which has been useful in evaluating factors contributing to improvement or deterioration of health and lifespan. I have been especially interested in estimation of effects of radiation in man.

SUMMARY

In natural radiation exposure and the extent to which it is increased by fallout, we are dealing with effects that are minute compared to other factors of importance to the health of man. Estimation of the magnitude of these small effects depends on determination of the dosages to be expected and the biological responses associated with these doses. This paper deals with the latter factor.

There is no direct evidence that doses as small as these produce any harmful effects; some have therefore jumped to the conclusion that they produce none. There is much evidence that a variety of undesirable effects occurs in cells, tissues, and whole organisms when exposed to doses large enough to establish either a positive or a negative result with reasonable confidence. Some of that evidence is presented here. Since it indicates an effect proportional to dose in the known range, the gap in the unknown range with which we are concerned is filled by arbitrarily assuming that the same proportionality holds. The principal justification for that assumption as a working hypothesis is that to ignore a small factor of risk, if it is real, may be costly if that small risk is applied to a very large population.

The similarity of the effects of all harmful processes, including aging, disease, and irradiation, has been expressed in terms of a concept involving an equivalence between units of the damaging agency and effective increase in physiological age over the chronological age. Factors obtained in this way may be used to estimate the cost in health and lifespan of any of the circumstances tabulated. As a present step, while recognizing the uncertainties of the assumptions on which it is based, the factor for irradiation may be used to compare costs and gains with respect to the atomic energy program. Much more effort should be devoted to the accurate determination of the quantities involved.

COMMENTS TO CONGRESSIONAL COMMITTEE, JUNE 1957

I am trying to evaluate every circumstance which can add up to or subtract from average human health and useful life span. Some of my colleagues jokingly refer to me as a prophet-of-doom because many of my estimates are best explained in measures of morbidity or mortality risks. This is how we must quantify human experience in order to evaluate factors that may truly be worth accepting or avoiding. It is not enough to know something is good or bad for us; we must express this knowledge in quantitative terms in order to be able to compare costs in health or life span with gains in other directions. Very fbrequently we accept circumstances having a known and measurable risk, such as using the bathtub, crossing the street, overeating, or riding a device for transportation, simply because doing so gives us some definite pleasure or gain that is reasonably more than the estimated cost in risk of harm. However, we are conscious of risk, in that bathtubs now are made with nonslip bottoms, streets have crosswalks and traffic signals, and our mechanical devices are made as safe as is thought to be warranted economically.

Since we are concerned here with the evaluation of radiation effects upon humans, I would like to tell you in some detail about interpretations I believe are reasonable estimates of this problem. I would like to separate information that is generally accepted from that based upon reasonable but debatable arguments; and I shall also use the evident uncertainty regarding answers to critical problems both as a caution concerning current interpretation of results and to indicate needed critical information. My concern for estimation of even minute effects places me at times in awkward situations—when quoted out of context, I may appear to be constructing "scare" stories. This I am not doing. Effects such as I have estimated are too small to be measured directly in individual humans affect estimated numbers of people only when large populations are subjected to the risks in question. Better estimates should eventually be made for each problem we can now discuss, but any estimate will have to depend on statistical studies of large populations.

I state definitely my summary belief that estimated effects of radiation from recommended occupational exposures and from fallout are minute costs compared to the gain to man of abundant useful energy and the extraordinary advantage we have gained for free nations by the awesome presence of effective atomic weapons. I would not, however, assume that, this formula for peace may continue to work indefinitely. Just as defense strategy, economic costs, possibilities for international agreement and other political, economic, and military factors are constantly reevaluated as circumstances change, the biological costs of the atomic age must be reappraised continually.

We all recognize that the world must find more energy to be used for human betterment. Many facts attest to this. Ten percent of the world's population is now using 90 percent of available energy and everyone—whether he already has much or little—wishes to have more of the material comforts made possible through the use of mechanical power. Populations everywhere are increasing, knowledge is increasing, need is increasing. In a world of dwindling available energy, humans very shortly would face a crisis of relative poverty. The availability of atomic energy promises instead a new age for man, marked by extraordinary technical progress that can be the result of both growth of knowledge and increase of efficiency. These asset values are well known; the liabilities are less definitely established. At the moment, we need to find out with much greater precision many basic facts of effects of radiation in man, the biologic costs of radiation exposure, how its effect can be minimized or avoided. It is quite evident that the problems that the atomic age has brought us are more complex than had originally been visualized. At the same time, it is true that the gain through atomic energy is considerably greater than was foreseen even a few years ago. While the physics, chemistry, and engineering of development of atomic energy needed and deserved the great attention they received, it is now evident that the factor of human tolerance of radiation needs further attention because of lack of precise knowledge regarding critical radiation effects. In my opinion, the next stage should emphasize a greater relative effort in this part of the problem, because it is imperative that we reduce speculation and establish estimates of biologic effects with more certainty. At the moment, in spite of the shortcomings of current information concerning these important problems, there seems to be no difficulty in continuing the development of atomic energy and at the same time accepting very cautious limits of radiation exposure.

Much of the information concerning radiation exposure as a problem to man developed almost wholly from the great sponsorship of this field of scientific inquiry by the Atomic Energy Commission. Many of the points currently under critical discussion, such as mutation rate associated with very low radiation doses or the quantitative estimation of fallout, might have been neglected had not those in authority shown a responsible comprehension of these problems and undertaken to support unusual costs as a part of the overhead of development of useful energy.

Now, I would like to present to you an outline of some of the facts and arguments that seem to be of special importance in current estimation of the effects of radiation in man. I wish once again to caution that, in these discussions, we are considering radiation risks that are very much like other commonplace risks to which we have long been exposed, such as driving automobiles—indeed, these newer risks are usually very much smaller.

Everyone wishes that risks to health and life might be reduced to zero. If that could be done, we would all live forever without growing old! Every moment of life, we face certain average risks of mishap—rarely of improvement. These average risks are the sum of many contributing factors, some large, some small. In individual affairs, very small risks are frequently regarded as no risk at all. On the other hand, in a popular presentation of hazards with a view toward emphasizing their importance, any risk that is greater than zero can be presented in a way that attracts concern, even though it may affect only one person in the entire world. A widespread exaggeration of hazards would, of course, have prevented any technical progress. I believe it would be an equally great mistake to dismiss, as being equivalent to zero, those small radiation effects we are now considering. It is true that most of these estimated effects are exceedingly small, and I can give many examples of ordinarily accepted circumstances that modify health to a much greater extent. The problem of differences of opinion derived from the same body of facts, is really the problem of deciding "how small is small," in the light of whatever is to be gained.

Similarity of radiation effect in mammals

In estimating radiation effects in humans, there is a striking similarity to observations established in experimental studies with animals. Cancer induction, radiation sickness, and genetic change occur at equivalent exposures. The average lethal doses are within the same range. Exposures causing burns or tissue damage are comparable. In general, this similarity would be expected from our understanding of the chemistry and physics of radiation effects and from the very similar structure of body cells of mammals of widely varying species. As an approximate truth, damage that is incurred by radiation exposure becomes more apparent as time elapses, so that for many effects, such as the induction of cancer, there is a latent period during which the effect of radiation is rarely observed. Roughly, the latent period for the induction of cancer is relatively long or short, depending upon the relative life span of the species. Thus, greatly simplified, the problem of making comparisons of radiation effect between, say, the mouse and man is a question of the relative time scale. Very similar relations in development of other diseases with time are observed between man and other mammals when time is expressed as a fraction of the life span. In such a comparison, the biology of aging in the mouse is remarkably similar to that of man, if one estimates 1 day's life of the mouse to be equivalent to 1 month's life of man.

Life-span-shortening effects of radiation

The conclusion from all studies of animal populations exposed to radiation in the range of 100–1,200 roentgens of whole-body exposure is that these dosages shorten life span. The shortening of life span of laboratory animals by these exposures is an established fact for either acute of chronic exposure. It is, however, distinctly unproven whether these effects apply on a relative basis to man, though the consistency for the many species of mammals tested lends great plausibility to this hypothesis. If we do make such an assumption, as I have done on several occasions since 1953, one obtains a number that suggests that the average human life span loss at a dose of 100 roentgens may be about 500 days, or about 1⅓ years. We can be certain that some number exists defining radiation induced life-shortening in man, but we cannot state the number with confidence. It can at best only be approximated. It is very important that we do learn what its value is, even though great effort and cost are attached to finding it. In the absence of definite knowledge, we must do the best we can to estimate this quantity.

In discussing this question, several additional considerations arise. Is life span loss proportional to radiation exposure? Most evidence can be interpreted in this sense, but not exclusively. It appears possible that life span loss may be somewhat greater than the above estimate at very large single doses, even though proportionality may hold in the small-to-moderate dose range. For very small chronic exposures, observation of the effect becomes very difficult and it is possible that no effect on life span may exist; however, current data are truly inadequate to test either hypothesis. Nevertheless, in mice, for example, a significantly enhanced and early appearance of tumors has been caused by exposure to 0.1 roentgen per day, the lowest dose yet studied for life span effects; and although no comparison with man can be made on this basis, it may be inferred that some effects occur at low doses. Even though the studies that enable us to speculate upon effects in this dose range have been extraordinary undertakings of technique and labor, we still need to have much more information of this kind to establish the bearing of radiation exposure upon life span loss. One of the most important points concerns whether exposure rate is a factor in the lower dose ranges, since it determines whether one may express this radiation effect in terms of loss per roentgen of radiation exposure. I feel that, with respect to large doses of radiation, the majority of evidence supports a concept that life-span loss is proportional to exposure; and, in the absence of human data on low doses and low rates of accumulation of dosage, it seems safest to assume that the same relation holds at these levels. On this basis, we might say that 1 r. of whole body radiation is perhaps equal to becoming 5 days older. In the absence of definitive information on radiation-induced aging in man, I believe it is reasonable to use this tentative number, even though it may be subject to revision as more certain information is acquired. Study of radiologists and atom bomb survivors may provide a better answer. In this regard there are conflicting opinions and reports. It has been evident for several years that radiologists have 6 to 10 times more leukemia than their expected rates.

Some additional studies of life expectation suggested shortened life span for radiologists. Dr. Shields Warren recently estimated that average age at death was 6 years less for radiologists than for other physicians. Thus, one might infer that radiologists have about 6 years shorter life span. Lewis has recently reviewed this conclusion and reports that, when the distribution of ages among radiologists is considered, the death rate for that group as a whole is no worse—and possibly better—than for physicians in general. However, by using both the individual ages of deaths provided to me by Dr. Warren and the number of registered radiologists, my colleague, Grendon, and I have constructed the age-specific death rates for radiologists. They are found to have the same death rate risk as the general population at ages under 60; but over 60, the death rate is about twice as high as expected. I had come to similar tentative conclusions several years ago by estimating approximate death rates of radiologists from obituary notices in the professional journals. I think it is reasonable to conclude tentatively that radiologists have a higher than expected death risk at older adult ages. This kind of evidence of radiation effect upon man is so important that a relatively great effort should be employed to make a precise study of individuals with known occupational exposures. It is true that the effects are probably very small but they are effects we need to know with relative accuracy, and such study is directly to the joint of estimating the effect of accumulating radiation exposures in humans.

What about dosage measurements in human studies of radiation exposures

Another crucial element in estimation of radiation effect in man is determination of exposure dose. Even though I believe that radiologists may have slightly shortened life span at older ages, there is considerable difficulty in correlating this estimate with a measure of exposure radiologists may have experienced to produce this aging. We simply do not know the average or individual exposures, and direct estimates of exposure can be stated only within rather absurd limits such as 100 r. to 5,000 r. of accumulated whole-body irradiation. There is the possibility, also that only a few greatly exposed individuals may be responsible for the extra deaths, giving a falsely high death rate to the entire group. Such difficulties also plague current attempts to evaluate findings among the Japanese survivors of atomic bombing. It is absolutely necessary to refine estimates of exposure of individuals in order to arrive at a proper evaluation of human life-span effects and to be able to test such data for proportionality or lack of proportionality of induced effects of exposure. A truly valid assessment of radiation effect in man has not been made and would require for its accomplishment the upmost in competent personnel and financial support, on a scale commensurate with its complexity. A great part of the potential and useful evaluation of effects of radiation in Hiroshima and Nagasaki is in jeopardy because too little is known concerning true exposure. The several evaluations of leukemia risk in these Japanese are in doubt because exposure is unknown and evidence for exposure is quite inconsistent with distance from the blast and shielding. Thus, the true magnitude of the leukemia-inducing effect of radiation may be very much smaller or larger than it is now estimated to be. With some effort, the dose might be estimated for accurately for those who developed leukemia and those who were in certain exposure categories. Many critical decisions concerning effects of radiation will need to be made, and it is important to have a proper number to apply in hte construction of these estimates. If such a number can be obtained by making an additional effort, I believe we should do so.

Proportional effects versus threshold effects in man

Attention to effects of radiation first established that there are acute effects, especially marked by tissue destruction, from which recovery subsequently takes place. Recovery in this instance is of the same quality as recovery from any usual kind of injury. As the amount of radiation given in a single dose declines, acute effects decrease more rapidly than the dose, because acute effects are due to tissue destruction and too little damage is done at any one site at doses of about 100 r. and below to evoke measurable systemic responses. Thus, there are some kinds of radiation effect that are not seen at doses of about 100 r. or less. These include immediate radiation sickness, death, burns, ulceration, hair loss, severe anemia, or sterility. All of these symptoms are largely the result of destructive effects of radiation upon rapidly dividing cells. Such cells for the most part are being replaced at a rapid rate, so that the loss of a small number may be quickly compensated. When radiation damage is considered in

terms of acute effects developing soon after radiation exposure, there is general and convincing evidence of at least partial recovery from the effects of exposure. Attention exclusively to this phase of the problem leads some to the opinion that human can tolerate single intense exposures to several hundred roentgens and subsequently recover all of the gross features of normal health.

As we direct our attention to injury of tissues or cells instead of confining it to whether an individual lives or dies, we find in general that effects of radiation are much more nearly proportional to radiation exposure. For whole categories of effects, such as genetic effects, destruction of cells, artifical aging of individuals, and induction of cancer, there is evidence—some completely convincing, some only a reasonable argument—that radiation effects at the cellular level are proportional to exposure to radiation. It is quite possible that some of the effects, such as the induction of cancers or of artificial aging, may not be as likely to occur per roentgen of radiation exposure at low exposures as at higher exposures. These points will be settled only by additional study of the problem experimentally in various animal species and by utilizing every opportunity to study chance human exposures. As a working estimate, it seems reasonable to postulate that effects at low dosage and low rates of dosage accumulation are proportional to know effects at higher doses. First of all, such a working hypothesis seems plausible in the light of the experimental evidence previously mentioned, and secondly, it is a cautious position to take to protect human health.

I believe that the general evidence relating biological effects to exposure shows a remarkable similarity between genetic effects and changes in cell numbers and cell quality in the other body tissues (somatic tissues). Muller, for example, argued as long ago as 1939 that the somatic tissue effects of induced aging and carcinogenic change were quite comparable to genetic effects induced by radiation, and that both effects upon the somatic cells were probably of the same kind as the genetic changes in cells measured directly by the geneticist. Radiation effects on various cells of mammals, such as genetic effects and the survival of cells, including germinal cells, blood-cell-forming cells, and embryo cells, roughly fall into a category of proportional effects of radiation in which the chance of effect is 1 to 3 cells affected out of a thousand, per roentgen exposure.

Radiation effects such as upon growth are quite in keeping with other effects at the cellular level, and human growth change comparable with experimental values of radiation growth suppression in mice. The sum of such evidence suggests that life-span changes and induction of cancers are accelerations of normal aging produced by decreases in cell numbers and cell qualities in amounts proportional to radiation exposure. The effect is frequently made more complicated, it is true, by the ability of the body to repair tissue damage through replacement of injured cells with functional ones; but, fortunately, this modification helps us to escape acute radiation effects.

Were it not for the simultaneous development of atomic energy and broadly supported studies applying to health safety, we would not be in today's position of understanding radiation induction of cancer and other effects to the point of realizing that we should estimate these effects at very low exposures. Only a few years ago, we would have assumed that such effects could not exist. Attention to the effects of radiation in the small-dose range means that these efforts will be extended and that the problem becomes much more difficult technically. It is important to emphasize, in addition to life-span-shortening and cancer-inducing effects, the effect of radiation from generation to generation and upon embryologic development, both of which may be effects that are proportional to radiation exposure into small-dose ranges; if they are, they need to be estimated in terms of human costs.

I would like to turn attention to some of the other environmental effects with which radiation exposure may be compared. For several years, I have been evaluating a large number of environmental circumstances collected from various sources in terms of effects upon the life span and death rate. A summary tabulation is given in tables I and II. The exact numbers attached to some of these effects are in dispute, because there are different choices concerning the estimated magnitude of the effect. Some of the effects are related to reversible circumstances as, for example, marital status, occupational hazards, metabolic disease; other factors, such as radiation exposure, are permanent. The latter class includes traumatic injury, childhood disease, and country of origin. Some of these estimated effects are additive; others are not additive because they are partial measures of the same problem. For example, if one estimates the effect of fat

metabolism on life span from consideration of fat-carrying molecules in the blood, this estimate will already contain the evaluation to life risk that can be obtained from obesity status; and, similarly, the cigarette-smoking effect is also evaluated by blood fats, so that these are not additive. Differences between males and females, urban versus rural dwelling, and national differences appear to be entirely additive.

Differences in life span in this list are given in terms of change of physiologic age. An individual in a category listed as +3 years—as, for example, when a person's mother lived to be 90 while his father lived the average life expectancy—is considered to have the death risk at any adult age of a person 3 years younger chronologically.

Such effects on life span can also be established for, say, automobile driving or employment in industry. The effect corresponding to recommended limits for human radiation exposure (as, for example, 50 roentgens of accumulated exposure in occupations) is very much less than any of these other estimates, perhaps being —0.7 year. The effect of fallout estimated by these methods to be about one one-hundredth of this value. It is quite obvious that each of these effects can be worth our attention, although the average person is not aware at any time that change is taking place. Even such effects as a difference of 10 years in physiologic age are quite unlikely to be noticed by the casual observer watching the tide of life from day to day. Detection of these effects is possible only by employing statistical tools, and the conclusions apply only to averages—not to any one specified individual, except in terms of the statistical concept of risk.

The additive nature of disease categories and factors underlying development of disease suggests a very important point with regard to radiation effects, namely that, even though we cannot reverse the effect of radiation damage itself, it should be possible to counter this effect by enhancing health in other ways. The general recession of disease and improvement of health over this century are clear evidence that great gains can be made in the direction of better health and longer useful life. Some of these gains may more than offset the adverse effects of radiation, and some of these gains may be expected to arise as the direct result of the AEC program in research.

TABLE I.—*Relative displacements of physiologic age by factors that accentuate aging or loss of life span (minus time) or retard aging (plus time)*

[8] As measured in 1900 (Beeton and Pearson). These effects may be measurably less now, as environment is changing to produce greater differences between parents and progeny. Also, in 1900, it was a greater feat than now to live to be 80 or 90.

[9] This 70 percent difference in distribution of lipoproteins, between 25 percent lowest and 5 percent highest, is equivalent to a total of 25 years in relative displacement of physiologic age.

TABLE II.—*Statistical distribution of lifetime shortening by travel and industrial accidents*[1]

[Calculation based on Vital Statistics of 1949, values for adult white males 20 years and older

All accidental deaths	−2.3 years per individual in United States of America.
Travel accidents:	
Accidents involving railways	−0.06 year per individual in United States of America.
Accidents involving ships	−0.04 year per individual in United States of America.
Motor-vehicle accidents involving driver and passengers.	−0.67 year per individual in United States of America.
Assuming only half of population spends appreciable time in automobiles.	−1.3 years per individual at risk.
Pedestrian motor-vehicle accidents	−0.2 year per individual in United States of America.
Assuming this effect largely involves the urban portion of the population.	−0.4 year per individual at risk.
Aircraft accidents	−0.05 year per individual in United States of America.
Assuming that ¼ of the population (actually, probably much less) uses airplanes.	−0.2 year per individual at risk.
Accidents involving industrial machinery	−0.04 year per individual in United States of America.
Assuming only 30 percent of males are employed using industrial machines.	−0.27 year per individual at risk.

[1] These values are based upon numbers of deaths attributed to accidents; the estimates of life span lost are actually perhaps slightly low because survivors who are maimed, and hence have reduced life expectancy, are not included in these estimates.

Dr. JONES. I will deviate from the prepared statement to save time. I can use the blackboard and anyone reading my ad lib remarks can fall back back on the prepared statement if he has difficulty following me.

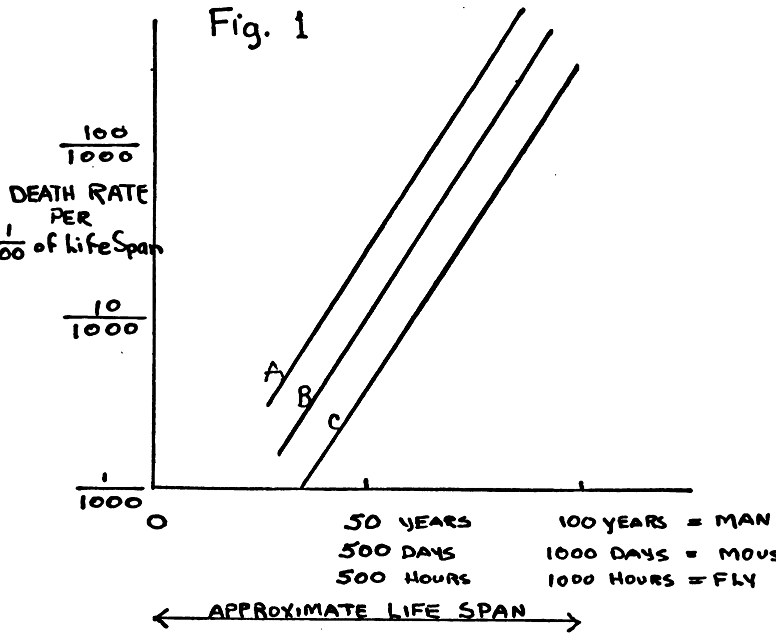
Representative HOLIFIELD. That will be fine.

Dr. JONES. My general problem in health research is to try to evaluate as many things as we can that have some bearing on human biology, human biology from the standpoint of the degree of good health we might achieve and how long we can maintain our life in relatively good health. These things can be expressed in terms of length of life, they also have to do with measures of death rate, because this is how we measure the risks of failing to remain alive.

I would like to present a diagram of this (fig. 1) because I think it helps to understand the problems of human biology. Ordinarily vital statistics for man are presented in units of death rates, that is, deaths per thousand of population per year. This level would be 1 death per thousand per year, this would be 10 deaths per thousand per year, 100 deaths per thousand per year, and so on.

I regret giving information in these terms because they are exceedingly morbid values to deal with. Sometime in the future I would like to turn them around and express them in units of vitality.

We are interested in the problem of vitality and not the problem of morbidity. If we draw this function (line B, fig. 1), this could essentially represent the aging of men or women of the United States. These are approximately the age-specific death rates. If we consider individuals at the age of 30, they have a risk of approximately 2



deaths per thousand individuals per year. At age 50, we find the death risk per year is 10 per thousand and so on.

We find this is a very regular sequence of events. It was described over 130 years ago by Benjamin Gompertz.

The very interesting thing about this is that if the horizontal distance represents life span of man in years, we can convert this equation to the biology of the mouse by changing the time scale to make the life span equal 1,000 days and then our line represents the aging of the mouse. The longer he lives, the larger the risk of dying.

One can also interpret the increasing death risk on the basis that physiologic degeneration is an accumulative affair. The more degeneration accumulates, the more likelihood there is of further decay; and the more decay in toto, the more the death risk. These concepts are relatively important to us because they may explain the very great differences in death rate between populations, either of humans or mice. If we plot the death rates for several populations of mice, we might get marked differences in death rate at each age (lines A and C, fig. 1). The interesting thing is that the biological equation always gives us the same slope. That is, the rate of progression of the death rate tendency is always the same for that species.

In this case, the death rate doubles for each age increase of approximately 80 days for the mouse, or approximately 8½ years for man. Otherwise, the equations are very much the same. The range of variations shown (a factor of 4) in death rate at any age occurs under average circumstances.

I can illustrate some of the differences among human populations. If we say this line represents death rates in the United States today, the Scandinavian countries are in a much better position, with lower death rate risk on the average. We can separate out some population

groups in the United States and find intrinsically low death rates, as good as those of the Scandinavian countries.

What has been happening? If we go back at least 100 years, say, to 1850, we find high death rates; and we find that over the course of the last century, throughout the Western World, death rates have been shifting in the direction toward lower and lower values, even though the rate of change of the death rate with age has remained characteristically the rate of change for man. This helps us to identify many factors that are probably of importance to us in a public health sort of way. I do not think that some of these things can be established with great certainty, but at least the effects of certain conditions have been identified as existing or not, which is quite important to us. One of the main things that has caused a shift from very high death rates in adult life to very low death rates at the same age, has been the recession of the childhood diseases. As childhood diseases have been eliminated, due to progress of nutrition and public health and medicine over the past century, we find that health in adult life has also been better and better, as evidenced by lower death rates.

We can identify a number of factors that have an effect on health. I will put some of them down. The recession of childhood diseases during the last century has added about 15 years of useful adult life. We can tentatively estimate differences associated with exercise—a deplorable thing to discuss when we do not get enough of it. The gain due to exercise might be of the order of 5 years. The effect of obesity, based on life-insurance statistics, is apparently proportional to extent of obesity, where 1 pound of overweightness is equal to 1 month of lifespan.

If you think of it the other way, if you are 1 pound leaner, it works in reverse or you have a 1 month gain.

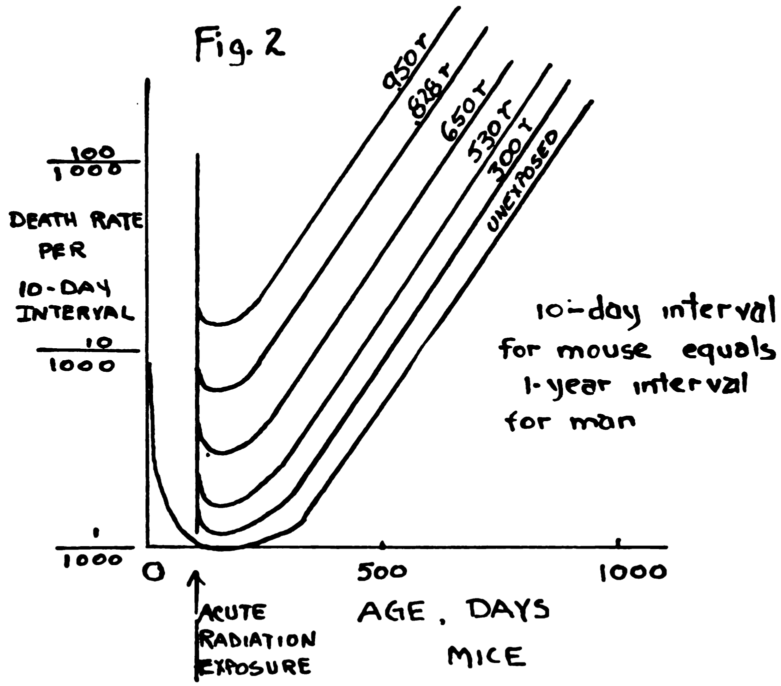
There are differences between living in the country and the city. There are very great differences between various population groups by nation of origin, not related to politics but to human environmental factors.

This type of analysis is important to us because it gives us a background to use with respect to the irradiation problem; particularly, if we look at the effects of irradiation on the mouse, we can use these same equations.. We will be talking in terms of a lifespan of a thousand days instead of the human lifespan of 100 years. The biology of aging of the mouse is like this [drawing on blackboard] (fig. 2). If we give single doses of radiation early in life, what we find is that the death rate goes up momentarily, due to the acute effects, and then, among the mice that recover, there is a displacement of the death rate just as though these mice were already older than they were before.

This apparent aging is the primary thing that characterizes the radiation effect on mammals; the general things that cause death are just about like the things that would have caused death anyway if the animals had been a little older. There are certain things that might really be specific for radiation toxicity, but in general radiation injury represents an increase in natural tendencies toward death. If we give twice as much radiation, this line would move up twice as far.

This brings us, then, to the concept of proportionality. As far as this kind of increase in the death rate is concerned, we seem to have a linear displacement that will move the line toward higher death

Fig. 2



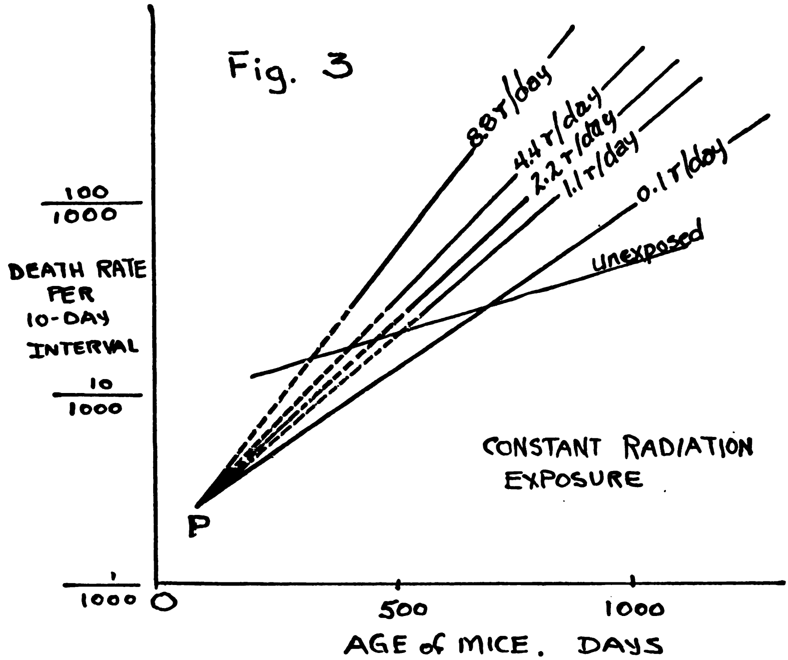
rates in amount proportional to exposure. The amount of injury, which is measured by the increase in death rates, is proportional to the amount of single-dose exposure between 100 and 1,200 roentgens. We can't go to higher exposures because the best techniques we have available will not enable these animals to live beyond the acute phase.

So this gives us one of the best illustrations of proportionality of radiation effect. Even so, there is a great deal of debate among my colleagues as to whether we should really conclude that these effects on life span are still proportional at very low doses. The reason for that is that the basic information we have to go on is relatively scanty. In spite of the fact that we would like to have better data, it has taken a great deal of effort on the part of most of our great laboratories to accumulate the information we now have.

Some of the experiments have been rather great undertakings in terms of numbers of animals, housing of animals, and the numbers of scientific investigators that have been a part of these studies.

A very large study was done in Operation Greenhouse, one of the atomic blasts in the Pacific, where large numbers of mice were used, and where we have good tests of the proportionality. Even in this case there was a difficulty in estimating the physical doses of these animals, and in the higher dose ranges it looked as though the effects on life span were relatively greater than at the lower dose rates. However, at the lower dose rates, the concept of proportionality still seems to hold in that the curve becomes a straight line which seems to go through zero effect at zero dose.

Some of the other difficulties in establishing proportionality of radiation damage are evidenced in terms of another effect that was demonstrated in mice, and that is the chronic radiation exposure ex-



periment of the late Dr. Lorenz. Fairly large numbers of mice were used in this study. In this case, when radiation is given constantly, one does not find that these lines are displaced in a parallel fashion; but, because the little increments of radiation damage are constantly being given, the line has a steeper slope, and the slope of this line will increase in proportion to the amount of radiation given.

So then, if radiation began at this point (point P, fig. 3) and we have varying dosages—maybe this is a tenth of a roentgen per day, this might be 1 roentgen per day, 2, 4, and 8—one can see that the change of death rate with age becomes steeper and steeper as we go to the higher chronic exposures. Unfortunately, with respect to interpretation of the results at the lowest dosages, the control mice were housed separately.

As far as the direct comparison of slope of the death rate curves is concerned, the unirradiated controls seemed to have a lesser slope than even the 0.1-roentgen-per-day group. But when the curves are put together, the control mice intersect in this fashion, (fig. 3), so that early in life the control mice had a higher death rate than the mice irradiated at 0.1 r. per day, and this variation essentially happened twice. So that the direct observation is that the animals that had a tenth of an r. per day lived slightly longer than those that had no irradiation; but the former group did have twice as many tumors as the latter.

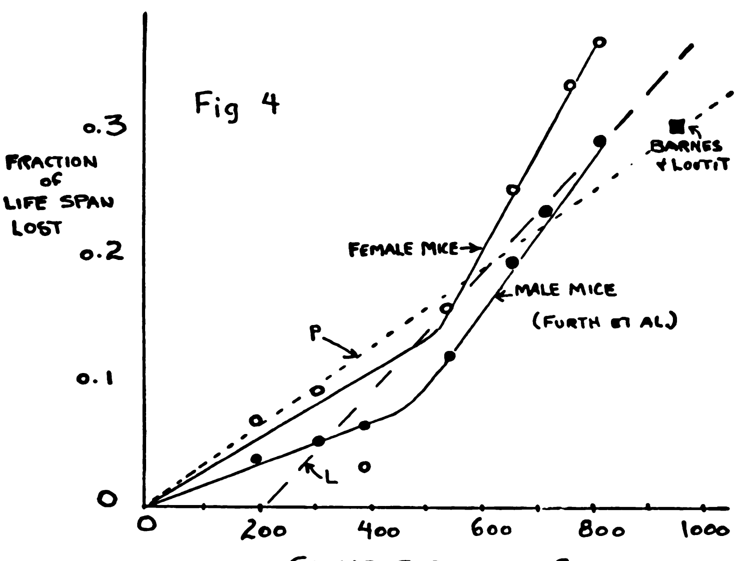
Such differences in death rate are seen quite commonly among animals that are housed separately in slightly different environments, in spite of every effort to make conditions identical. In such cases, however, the slope of the line has remained the same, but the position of the line has been displaced.

I don't know any way out of this particular dilemma except to get further information from repetition of these experiments. The anomaly has given some people a bulwark to fall back upon in arguing that perhaps there is a threshold in terms of radiation effect on the life span. On the other hand, I would place little confidence in this argument, because these animals were housed separately.

Representative HOLIFIELD. What do you mean housed separately and controlled?

Dr. JONES. The experimental mice were chronically irradiated, so they could not be kept in the same room or region of the building as the control mice, which are kept in a normal environment for comparison. They had to be housed in a different room. These particular control animals were even raised at a different time period because the animals that were contemporary with the mice that were irradiated happened to have an infection and the colony was lost. This limits the interpretations one can place upon these experiments.

Even so, expected effects of 0.1 r. per day are so slight, and the numbers of animals are so small, that the results do not let the investigator test significantly either way whether the effects of irradiation on life span are subject to a threshold or are continuous in the small-dose range (fig. 4).



Solid lines are best fit, aging proportional to dose
LINE-P, possible fit, aging proportional to dose
LINE-L, possible fit, aging beginning at a threshold of 200 roentgens

So we have to conclude in general that there is no direct evidence of life span effects in the small-dose range. We can only draw inferences from effects at higher doses. But I believe if we add everything we have available in the higher dose range, of the order of 100 r. up to 1,000 r., that the effects seem to be reasonably proportional to

radiation exposure. Just as the geneticists have trouble in going below 25 roentgens in testing proportionality, I think we have trouble going below 100 r. in establishing that life span effects can occur at very low doses. It is certainly possible to test for radiation effects in this region, but it will be difficult and the testing will not be completed for some time to come.

I also think that everywhere possible we should make an effort to obtain such information directly from man. Of course, there is the study of the Japanese. There is also the study of the radiologists that we discussed briefly yesterday. These studies have some limitations. If one makes the best estimation possible of the death rate for radiologists and compares it with the white male population, it does appear that up to the age 50 the population of radiologists and the white male population have similar death rates. Above this age, the death rate of radiologists is increased above the general population, so that the displacement in death rate, which corresponds to age, makes radiologists effectively at least 10 years older than nonradiologists of the same chronological age. This really only tells us that a life span effect of radiation can occur in man. It is very difficult to say what the ratio of life-shortening to radiation dose is.

It is very difficult to say what the exact number is because the numbers of radiologists have been increasing in each year's time. Over the last 20 years, the number of radiologists has increased by a factor of 3 or 4. With this increase, there has been an increase not only in the younger ages but in all ages. So we have no idea as to what the average dose of radiologists may have been. We can only guess that this 10-year difference in aging is associated with an average dose of somewhere from 200 r. to perhaps as much as 1,000 r. I personally doubt whether this 1,000-r. value taken as an upper limit could really be expected, because I think the effects of 1,000 roentgens of whole body irradiation would be more severe than we see it in the average radiologist.

There is, however, very little doubt that many of the radiologists who are responsible for this higher death rate are really groups that had much greater than average irradiation, and that the main population of radiologists having much less exposure than these few are really subject to a lower death rate.

It is also important at this time to point out that we really need to have a value that we can say represents the effect of radiation on the life span of man. The best thing we can do directly in the absence of such a number, I believe, is to estimate it from the mouse. Unfortunately, we know so much about the biological equations of aging, how diseases develop in both the mouse and man, that we can use this system of simply converting 100 years to 1,000 days to give us this information directly, and use it with whatever confidence limit needs to be applied, remembering that the information is from the mouse.

When we do that, we will find that, taking the mouse data directly, we might conclude that 1 roentgen perhaps—and the "perhaps" is big—is equal to minus 5 days in terms of individual life span. On the average, the individual exposed to 1 roentgen would be like an individual without this amount of radiation who was 5 days older. You see, for all practical purposes within the model as constructed, radiation exposure simulates the ravages of time. So we are justified from the standpoint of the general logic of these events in making this conversion between roentgens of exposure and units of life span loss.

But this is not all. This value, within the confidence limits of the data, might truly range from 1 day to greater than 15 days. We simply don't know. I would advise us all to look at the problem as carefully as possible and use whatever means we can to get such information.

While I cannot be certain where this value may truly lie, the sum of all information I have available to work with would lead me to trust tentatively as a direct average without weighting it for any factor at all this value of 5 days. If we look at the Japanese data in terms of death rate, it is possible that these will fall somewhere within the liimts of 1 day to perhaps greater than minus 15 days per roentgen. We simply do not know yet.

I had occasion to make some very rough estimates some time back and all I could say was that it looked as though there was a life span loss on the Japanese. As we know, there is quite a leukemia rate associated with it, similar to the increase in leukemia rate in radiologists.

Very briefly, I might examine a few factors that are perhaps related to the shortening of life span. They may help to explain radiation effects. I think this particular result of radiation is possibly due to some combination of two effects: the tendencies for the cells to undergo mutations, such as Dr. Muller and others described as somatic mutations, and also the reduction in numbers of functional cells in the animal. If we look at the numbers of functional cells in the animal, or the effects of radiation on mutation rate, we would be looking in effect at a corresponding increment of the death rate. If we look at the cells directly in terms of the response to radiation. for many cells in mammals we will find that there is proportionality in numbers of cells left alive, and number killed per roentgen.

From a lower value of 10 roentgens up to values of 2,000 roentgens in the rat or in the mouse or human blood cell estimates, it appears that, per roentgen in this range, you would have between 0.3 percent and 1 percent of the cells killed. It looks as though the effect of radiation in mammals under a variety of circumstances, for cells like the marrow cells or lymphatic cells, is within this range.

Also, the cells in the developing embryo, which also have a high rate of cell division, have approximately this same range of radiation sensitivity. We can show that the small effect of radiation on the growth of children irradiated before birth in Japan is about the same rate as this, 0.3 percent per roentgen, and this turns out also to be equivalent to the data that Dr. Russell described a moment ago on his irradiated mice. So we have some general idea that in the various mammals we can study, the effect upon cell numbers seems to be relatively the same among the various mammalian species, and also the life span effects seem to be roughly the same as far as we can test; but it does leave us with the great desire to know much more about these effects, and also to know what kind of number we should estimate for the life-subtracting effect of radiation in man.

Senator HICKENLOOPER. Do I understand that range you put on the board a moment ago from 10 roentgens to 2,000 roentgens, that an exposure of 10 roentgens would kill 0.3 percent of the cells and exposure of 2,000 roentgens would kill 1 percent?

Dr. JONES. The range of 0.3 percent to 1 percent of cells killed per roentgen applies throughout the range from 10 roentgens to 2,000 roentgens. One has to interpret the proportionality in what we call

the hit equation. You cannot kill the organism twice. So that in upper doses very few cells are left untouched.

Senator HICKENLOOPER. That is the thing that confuses on that statement. I would interpret what I understand you to mean that as compared to an exposure of 10 roentgens and 2,000 roentgens that the 2,000 roentgens would kill only about 3 times as many cells percentagewise as the 10 roentgens. That is my understanding of your statement.

Dr. JONES. No. If we test for this range where we have available data in the mouse, regardless of whether we give 10 roentgens or give 2,000 roentgens, we will find that we have 0.3 percent of the cells affected per roentgen. So that, per roentgen, as far as the effect on rapidly dividing cells is concerned, it will be three cells of each thousand cells affected.

Senator HICKENLOOPER. I understand. I missed the equation to the single roentgen.

Dr. JONES. Yes. The remarkable thing is that this is such a good proportionality effect.

Representative HOLIFIELD. Dr. Jones, we want to adjourn at 5 because the committee has to go into executive session on another matter.

Dr. JONES. I can summarize this section. I think life-span effects do exist. I have no reason to doubt this at all. I have some reason to believe that we should look with caution on the argument that a threshold effect exists, although we cannot be absolutely certain that a threshold effect might not exist. But as far as my opinion is concerned, on the basis of having examined all the facts at my disposal, I do not believe a threshold effect is very likely to exist, I think we should try to get better information, not only for this point, but also to find out directly in man how much each unit of radiation subtracts from life span, because in an atomic age everyone is going to need to know this number with a great deal of certainty. At least, it should be determined to 1 or 2 significant figures and not merely within the range of perhaps a factor of 10.

Representative HOLIFIELD. Thank you. Your summary is very interesting, and the statement that you have submitted will be studied carefully.

I have two papers by Dr. Jones that I would like to place in the record at this point.

(The material referred to follows:)

A SUMMARY AND EVALUATION OF THE PROBLEM WITH REFERENCE TO HUMANS OF RADIOACTIVE FALLOUT FROM NUCLEAR DETONATIONS

Hardin B. Jones,[1] Donner Labortory of Biophysics and Medical Physics, University of California, Berkeley, Calif., January 14, 1957

ABSTRACT

The tolerable amount of radiation exposure to humans is probably less than formerly estimated. It is shown, however, that accumulated effects of the low-level worldwide exposure to radiation from fallout to date is relatively small. The genetic effects are not large enough to be statistically detectable. The health effects, as expressed in life expectancy, are much smaller than those of such factors as infectious or chronic disease, metabolic disturbances, smoking, obesity, lack of exercise, and environment and marital status. Predictions of strontium 90 levels to be expected in the next 2 decades indicates, however, that bone irradiation may become detectably harmful.

[1] With suggestions and critical review gratefully acknowledged to R. Lowry Dobson, John W. Gofman, John H. Lawrence, Burton J. Moyer, William Siri, Curt Stern, and Edward Teller.

INTRODUCTION

Nuclear detonations form radioactive isotopes in quantities so enormous that they must be reckoned in terms of many thousands of curies, the equivalent of many pounds of the element radium. A portion of this radioactivity is dispersed into the atmosphere and subsequently falls upon the land and sea. However, the vastness of the land, air, and water of the earth provides a means of dilution so great that even these large quantities of radioactive materials are soon reduced by distance and time to exceedingly small concentrations of radioactivity. The problem of radioactive fallout in relation to human beings involves the need to know the quantity that becomes a part of human environment, and to know the effect upon man of ionizing radiation from fallout.

This summary concerns low-level worldwide fallout. It must be recognized, however, that very intense fallout may be experienced in the vicinity of an atomic detonation. For example: [3]

"On March 1, 1954, an experimental theromonuclear device was exploded at the United States Atomic Energy Commission's Eniwetok Proving Grounds in the Marshall Islands. Following the detonation, unexpected changes in the wind structure deposited radioactive materials on inhabited atolls and on ships of Joint Task Force 7, which was conducting the tests. Radiation surveys of the areas revealed injurious radiation levels; therefore, evacuation was ordered, and was carried out as quickly as possible with the facilities available to the task force.

"Although the calculated accumulated doses to the exposed human beings were believed to be well below levels that would produce serious injury or any mortality (267 Marshallese received 14 r. to 175 r.) * * * All of the exposed individuals have recovered from the immediate effects (burns, loss of hair, anemia) without serious sequelæ. Nevertheless it is planned to evaluate the medical and genetic status of the group at appropriate intervals with a view to learning what if any of the known late effects of radiation exposure may be observed. Obviously and indeed fortunately the number of persons (92 Marshallese) receiving 75 roentgens exposure and greater is too small to make it possible to determine with any degree of accuracy the effect on life span."

EFFECTS OF RADIATION EXPOSURE IN HUMANS

The reasonable and superficial evaluation of radiation hazard is that humans can obviously tolerate exposure to several hundred roentgens, recover from immediate effects, and remain in "normal" health and functional capacity. Recently, however, we have become aware of deleterious long-term effects of radiation which, however subtle, appear to be proportional to the total quantity of radiation exposure and may be assumed to act even at very low levels of irradiation. Except for these long-term changes, our understanding of radiation effect usually has been concerned with two important facts that dominated our thinking about these problems:

(*a*) For certain kinds of radiation damage and injury, there is recovery. Individuals recover from acute symptoms produced by sublethal radiation exposures even though they may show general sickness, burns, loss of hair, anemia, etc. Recovery from acute radiation effects is analogous to recovery from any other acute injury or infectious process in which damaged tissue is healed and repaired.

(*b*) These obvious signs of radiation effect are associated with relatively large single doses of radiation (greater than 100 r.). As dose size is decreased, detectable acute effects decline, becoming disproportionately small, so that there is a true threshold of dose of irradiation, at about 100 r., below which these particular acute manifestations of radiation do not occur.

THE PROPORTIONAL-EFFECT CONCEPT OF IRRADIATION

Recent evidence that long-range effects of radiation simulate aging effects comes from a variety of sources and is consistent with information relating radiation effects with genetic change and changes in cell-population numbers and quality. Evidence and logic support an argument that small increments of radiation-induced morbidity persist as small permanent changes in body functional struc-

[3] Quoted from Charles Dunham, A Report on the Marshallese and Americans Accidentally Exposed to Radiation From Fallout and a Discussion of Radiation Injury in the Human Being (United States Atomic Energy Commission, July 1956).

tures, which become detectable as aging, neoplastic disease, and genetic change (see appendix A). However, it remains to be proven experimentally that these effects do occur as the result of small irradiation exposures. The testing of this question is not likely because it would involve great technical difficulties. Attempts to procure some evaluation of the problem relating small-doze (5 r. to 10 r.) effect to life span would involve study under uniform conditions of perhaps several million mice. It is pointed out that in order to establish the effect of the smallest doses as yet measured for genetic effect, namely 25 and 50 r., the geneticist Curt Stern and his associates worked for 6 years and examined approximately 50 million individual flies. They came to the acceptable conclusion that these small exposures have the same effect per roentgen upon gene mutation as at higher exposures to radiation. Ionizing-radiation effect, in the depression of blood-forming function and blood-forming cells, is proportional to radiation dose even down to 5 r. (Hennessy and Huff). Other effects upon blood cells, leading to abnormal doubling of the cell nucleus, are now reasonably established by Dobson in the range of 0.1 to 0.3 r. of single exposure, but are not yet tested for proportionality.

There is no reason to doubt the general evidence of a proportional effect of radiation; but it is also possible that linear extrapolations of higher doses to the small-dose range may not give a true representation of the problem. It is known for some kinds of cellular response to radiation that there can be no effective change in function until two or more similar critical entities within the cell are affected. Some kinds of observed injury, however, appear to depend upon the effect on one critical entity per cell; and other observed injuries may be the result of damage to any one of a number of critical functional parts. The response that depends upon a chain of two or more detrimental changes shows a lesser apparent effect in proportion to radiation exposure at the low-dose ranges. Although this kind of irradiation response does not argue against extrapolation of radiation effect, it may explain a factor of —2 or —4 buffering against detectable radiation effect in the lowest exposure ranges; or it may even have the opposite effect, because radiation effect can add onto partially initiated dysfunctional changes in structures that otherwise would have remained functional.

Radiation effect is most frequently estimated in animals that are rather uniformly irradiated over the whole body. Thus, we are usually generalizing from the observed result of whole-body exposure. In some studies (Kaplan), shielding a relatively small portion of the bone marrow from radiation may protect the animal from generation of thymic tumors. In others, local irradiation is associated with induction of cancer in that region, quite independently of exposure or shielding of the remainder of the body.

The problem of estimating radiation effect and making recommendations concerning it is not the simple problem of avoiding exposure at levels at which there is a detectable or predictable response. This is especially true when considering radiation effect through systems that allow proportional extrapolation to very small radiation exposures. It is always important to keep radiation exposure to a minimum; but it is also important in the understanding and evaluation of the relative importance of radiation effect to establish its place in the entire climate of factors that can modify health. Similar—and, at times, greater—effects upon health can be shown to result from a large number of common environmental factors.

Also, the problem is not simply that of effect of body irradiation upon health. It is necessary to evaluate the effect upon human beings of all known phenomena resulting from the onset of the atomic age, including general socio-economic factors related to our well-being, which are dependent upon progress and the development of useful energy.

ADVANTAGES MINUS COST EQUALS NET GAIN

The sum of evidence would lead to the conclusion that radiation probably does affect man's health subtly, and—like money and time—it should be exchanged for equivalent advantages.

Since the usefulness of atomic energy—including material and energy gain and defense measures of prime importance—is a positive result, and the radiation effect upon humans generally is a negative result of the atomic age, atomic-energy usefulness minus harmful radiation effect must be equated to the net gain. Therefore it is critically important to estimate hazard quantitatively, and to be mindful of other factors while doing so. However, there is no unanimity of opinion at this time as to the precise balance that should be achieved between advantages and disadvantages of use of atomic energy, because certain

qualifying factors are still too poorly known. Uncertainties exist which can mean either underestimation or overestimation of the effect of radiation. This brief synopsis roughly appraises the biological costs of exposure to radiation and presents information which must largely guide decisions in the interim until more precise information on radiation effect is available.

A summary of current knowledge of radiation tolerance or hazard and fallout is provided in several major public documents that have appeared in 1956 in broad survey of the problems to man of atomic radiation and fallout.[3 4 5 6 7]

THE CONCEPT OF MAXIMUM PERMISSIBLE DOSE

Early estimates of that amount of exposure to ionizing radiation which constitutes a permissible occupational hazard placed the upper limit at 0.1 r. per day. Such a value was exceedingly conservative in view of information available at the time it was established. It is lower by a factor of 50 than chronic exposures leading to physiological disturbances and radiation sickness, and by a factor of 1,000 to 5,000 than the dose which, in a single exposure, might threaten life. Also, at the time it was proposed, 0.1 r. was the lower limit of radiation exposure dose known to elicit any biological response. Evidence on the magnitude of physiologic response of the individual to radiation in the range of a few hundred roentgens has not changed; but extensive information on effects of lower levels of radiation has recently appeared. This knowledge requires a reevaluation of the cost to humans of radiation exposure in terms of (*a*) genetic effects, (*b*) shortening of lifespan, (*c*) induction of cancers, (*d*) destruction of tissue, (*e*) congenital malformation, and (*f*) effects upon young individuals. All these effects appear to be proportional to the exposure to radiation, and have been largely responsible for a recent downward revision in maximum allowable exposure to radiation.

THE GENETIC EVALUATION OF RADIATION EFFECT

Up to 1946 estimations of the genetic effects of radiation had placed the quantity necessary to double the mutation rate per generation in the fruitfly at about 50 r. (Muller, Stern), but with some uncertainty, so that the true value might have been 80 r. or 35 r. At that time, there had been relatively little comprehensive evaluation of the range of genetic sensitivity to radiation in mammals or man. At the present time, the mutation rate per generation for the fruitfly is known to be doubled over the natural rate by about 50 r. (Stern). Through genetic study of irradiated mice (Russell), the amount required to double mutation rate per generation in the mouse is partially established also at approximately 35 to 80 r. Wright has estimated from evidence now available that the mammalian mutation rate may be doubled by as little as 3 r. or as much as 300 r. The best current estimates place the mammalian mutation-doubling dose of radiation at about 50 r. (4).

As an approximation, each species appears to form in natural circumstances about one new mutation in a generation time. The fruitfly lives a short time in about the same radiation environment (estimated roughly at 0.1 r. per year) as man. In its life span of 20 or 30 days, it can accumulate only the minute quantity of 0.008 r. Thus, if 50 r. in the fly produces an additional number of mutations equal to those which occur naturally, radiation can account for only a part of the natural mutation frequency, namely, the fraction

$$\frac{0.008}{50}=\frac{1}{6,000}.$$

Hence, at background radiation, only 1 observed mutant in 6,000 is suspect of being induced by radiation. In humans, the life span up to average reproduction age is about 30 years, lived in the same environment of 0.1 r. per year, or a total of about 3 r. by average reproduction age. Thus, if 50 r. is estimated to double the human mutation rate, radiation from natural sources may be expected to account for

$$\frac{3}{50}=\frac{1}{17},$$

or approximately 6 percent of the naturally occurring mutations. If we accept the lowest possible value of 3 r. for the mutation-doubling dose, we would have as the fraction attributable to radiation

$$\frac{3}{3}=1,$$

and radiation could account for the entirety of mutation changes in humans.

The fallout of radioactive materials through 1956 has increased the radiation exposure of gonadal tissue by an amount estimated as approximately 0.004 r. per year (see table V–D) (largely from ingested cesium–137 (4) and deposits on the ground (6)). This is an increase of approximately 3 percent over natural radiation exposure.

The recommended limits of radiation exposure in man will be affected by information on the quantitative relationship between ionization and mutation and the understanding of the natural mutation burden. Should we estimate the level of radiation likely to double the natural mutation frequency in man as 25 r. or 3 r., we will be at least 2 to 20 times as concerned about the genetic problems associated with radiation exposure as we are under the current assumption that the human mutation rate is doubled to 50 r.

Genetic studies of irradiated Japanese have been carried out by the Atomic Bomb Casualty Commission at Hiroshima and Nagasaki. A 10-year study has been analyzed by S. V. Neel and W. S. Schull.[8] The principal result is that no measurable increase in mutation rates was observed. They measured biological characteristics that could reflect genetic state and genetic change, such as stillbirths, male-female birth ratios, and congenital malformations. The results of all observations of this kind can be interpreted either as demonstrating no measurable increase in these events, which are associated with mutations, or as showing that, had the true congenital malformation rate been doubled, there would be only 90 percent probability of discovering even this increase. Thus a small increase in congenital evidence of genetic change would not have been detected.

The results of the study of the Japanese indicate that the human genetic effect of radiation is acceptably consistent with the range of response estimated from mammalian genetic experiments; and it establishes with certainty that there are no catastrophic genetic effects at low to medium range of radiation exposure in human beings, although catastrophic effects are predicted at high levels of accumulated radiation exposure to whole populations. Many new mutations were probably produced in the Japanese exposed to the atomic bombs; but many of these may have been unobserved because of early lethality, and the rest are overwhelmingly diluted by the vast number of normal genes. This dilution was expected; and the statistical odds are known to be very greatly against the appearance of unfavorable and detectable combinations of mutant genes in any one generation of offspring.

Genetic change is, of course, basic to the concept of the Darwin principle of evolution. For this reason, it is possible that some increase in the mutation rate might be to human advantage in the long run by providing a greater pool of variance from which selection could take place, to our final advantage some thousands of years from now. Some brief speculation regarding the extreme limits of variation may be offered:

(*a*) Humans and other long-lived animals have, as a corollary of their longevity, a less frequent natural mutation rate per gene per unit of time than short-lived species. As an approximate rule, each species appears to have about the same mutation rate per generation time. Thus, it appears that species are in some balance between generation time (or lifespan) and stability of genetic structure.

(*b*) Testing biological capacity for survival under circumstances that increase genetic variation is possible only with species having relatively short generation times. They have a common feature of a potentially great ratio of progeny per parent. These species can therefore survive even if a relatively high proportion of conceptions are incapable of survival and reproduction. Humans in natural selection are at some disadvantage in comparison with species producing a large number of offspring per generation, such as the mouse or the fly. Thus, human

[8] Reported at the First International Congress on Human Genetics, in Copenhagen in August 1956.

genetic tolerance should not be judged from effects of radiation exposures on these more fertile populations.

(c) For survival of a species, the ratio

$$\frac{\text{Reproducing offspring}}{\text{Individual}} = \text{must exceed } 1.$$

In humans, lowering of infectious disease toll has brought this ratio to approximately 2. As a consequence, the human population is now doubling in numbers approximately every 40 years. Thus, humans have already achieved some protective reserve against genetic changes toward lower fertility.

(d) On a scale of catastrophic genetic misfortune, humans also have the protection of vast numbers of individuals. There are 2.6 billion inhabitants of the world. While this number is small compared with numbers of insects and small mammals, it is still a very large number compared with that of any previous age in the history of man. Radiation exposure, as a cause of genetic change and increase of genetic variance, would be expected to produce that change in a random way. Thus, even with a large increase in genetic variance induced by radiation exposure, if population numbers are sufficiently great, some individuals will remain relatively unchanged. If these individuals were favored in selection, they might replace the less fit, less fertile fraction of the population. Thus, if survival of mankind were the only consideration, population numbers might, through reduction and segregation, achieve selective retention of adequately functional humans.

Several approaches to evaluation of extreme tolerance of human populations to radiation exposure with respect to health and genetic constitution are presented in appendix B. These methods of estimation are difficult and speculative; but they indicate that an additional 2 r./per year (or 50 r. per generation time) of chronic radiation exposure to the average individual in the human population would eventually cancel health and lifespan gains we have achieved recently. Such estimations of impairment of health and estimations of the cost of increasing the genetic variance suggest that human population cannot afford the biological cost of this intensity of chronic radiation exposure, and that there should be extreme caution at this time against increasing the radiation exposure to all people by 10 times over its natural level.

Evolutionary benefits?

It seems possible that human evolution is occurring in some optimal balance between mutation tendency and genetic stability. Fertility, length of life, death rate, and individual usefulness may be highly affected by the number of accumulated new genes,[9] which both add to favorable evolutionary drift in average human vigor and add to the pool of undesirable genes to be selected against. At low radiation levels, such as 10 percent or 1 percent above the natural radiation background (the range of fallout effect), it seems unlikely that long-range genetic disturbances can become an appreciable problem, since the natural radiation background appears to account for only 10 percent of the change in genetic structure per generation. One may speculate further that, in the long run, man may be beneficially affected by good genes yet to be formed, so that increasing radiation exposure and the mutation rate may operate to human advantage. Such an argument is unlikely to convince men who understand some of the dangers of too great a burden of undesirable mutants; it is analogous to an attempt to convince the experienced cook that the baking of her prize cake would be accomplished in half the time at higher oven temperature.

Penrose has evidence of indirect beneficial effect of some recessive lethal genes, which appear to enhance the effect of the functioning gene with which they are matched in individual combinations. This effect is one in which mutation may beneficially add some variance to genetic functional characteristics. On the whole, however, there is a strikingly large mass of information indicating that any genes that can disturb function should be kept to an absolute minimum.

Unfortunately, there are still many unanswered questions facing geneticists on the topic, "What is the effect of undesirable genetic burden on the quality of humans?" Fully satisfactory experimental measures have yet to be applied to this problem. One approach that has led to considerable speculation is through

[9] Transformed genes are, with rare exception, nonfunctional, lethal, or undesirable.

estimations of the numbers of undesirable mutations carried by the average person. Estimations of this burden place it within the small range of 5 to 15 undesirable genes per average individual[10] (4). This value is the equilibrium resulting from approximately one such gene gained and one lost in each generation.[11] Thus it has been pointed out that if, through increase in radiation exposure, the genetic gain of undesirable genes increased from 1 per generation to 2 per generation, there would be a relatively great reduction in the quality of the best 25 percent of individuals (assuming that reduction in quality of offspring is proportional to the number of undesirable mutations per individual). Because of speculative—but reasonable and cautious—arguments of this nature, geneticists have uniformly cautioned against allowing any major proportion of the population to accumulate radiation as high as 50 r., which is the amount estimated to double the human mutation rate.

LIFE-SHORTENING EFFECTS

Life-shortening effects of radiation have been observed under a variety of experimental conditions. An experiment of particular significance because of the large numbers of animals and the range of exposure was the exposure of mice to nuclear detonation at "Operation Greenhouse" (Furth et al.). The fraction of life span lost per unit of radiation exposure appears to be essentially the same for a number of species, including the mouse, the rat, the guinea pig, the rabbit, and man. The largest number of experimental observations concerns the mouse. In the mouse, the fraction of the life span lost per unit of whole-body radiation exposure is acceptably constant over a wide range of variation in radiation exposure. The tentative conclusion is that radiation effect simulates aging itself, and that a unit of radiation exposure, regardless of the intensity and duration of exposure, produces approximately the same relative disturbance to body structure in adults of all mammalian species. On the human life span scale, these effects of radiation summarized from small-animal data suggest that 1 r. of radiation exposure is equivalent to 5 to 15 days of physiologic aging. This prediction is confirmed directly in man (with reasonable technical reservations) by Dr. Shields Warren's recent investigation of life span of radiologists compared with physicians not using radiation in their practice of medicine. The average age at death is approximately 6 years less for radiologists than for physicians in general practice or for pathologists, both selected as being relatively unexposed to radiation. The estimation of accumulated radiation exposure in radiologists is uncertain, but has been approximated as 300 to 500 r. Thus, the life span loss, if attributed to radiation, is

$$\frac{-6 \text{ years} \times 365 \text{ days/year}}{300 \text{ r to } 500 \text{ r}} = -7 \text{ to } -4 \text{ days per r of whole-body exposure}$$

Such a number is still subject to considerable possible revision; but many different estimates give values of 1 to 30 days lost per roentgen of radiation exposure, and the probable value for humans is in the range of 5 to 10 days lost per roentgen.

A question exists whether we can justifiably extrapolate effects such as life-span lost per roentgen from measures that are mostly determined in the range of 100 to 1,000 r. The evidence is that, over the range that can be tested, the effect is linearly proportional to the radiation exposure; and the information fits an extrapolation to zero shortening of life span at zero artificial radiation exposure. There is additional evidence in the effects of radiation upon cells (as distinguished from entire organisms), in which lethal damage to cells per roentgen also appears to be proportional to total radiation exposure. Such estimates agree for cells in the mouse, the rat, the rabbit, the guinea pig, and man. This

---

[10] Some individuals may have none. The fraction having none or very few diminishes steeply with increasing average numbers of undesirable mutations. Thus, doubling the burden of mutations may reduce the numbers of individuals having desirable genetic combinations to rare events.

[11] The average mutation frequency of 1.5 spontaneous mutations of human genes per generation, as summarized by Penrose, corresponds to 30 mutations per million genes per generation, assuming that humans have about 50 ;000 genes:

$$\frac{30 \text{ mutations per generation} \times 50{,}000 \text{ genes per individual}}{1{,}000{,}000 \text{ genes}} = 1.5 \text{ mutations per individual}$$

per generation.

The average mutation rate may be less than this estimate, since one may suspect that the genes usually observed to mutate are perhaps 10 times as mutable as the average gene.

experimental evidence that effect of radiation on cells is in linear proportion to radiation exposure of from 15 to several thousand roentgens provides a reasonable basis for understanding the life-shortening effects of radiation.

Furthermore, the life-shortening effects are consistent in order of magnitude with the genetic effects of radiation upon cells (2 to 3 cells affected per 1,000 cells per roentgen). The genetic effect of radiation has been shown to be acceptably proportional to radiation exposure from 25 r to 8,000 r.

The sum of systematic evaluations of such effects of radiation as mutation induction, cell destruction, and life-span shortening indicates that these effects are permanent and represent the quantum interactions of radiation randomly affecting body cellular structure. The concept of quantum interactions with matter justifies extrapolation to the probability that a single quantum of radiation reacts with an individual molecule.

Although all recent evidence suggests that radiation effects is proportional to radiation exposure, such effects must be viewed together with other common environmental factors that modify health. A scheme is used here in which the effects upon health is expressed as an induction of aging (this is expressed as loss in physiologic lifetime, or minus time, written "—*n* years") or as a postponement of aging (expressed conversely as lifetime gained, or plus time, "+*n* years").[12] These factors all appear to have a general action upon disease tendency, and the effect is about the same at any adult age. The list of relative displacements of physiologic age (table I) is given for factors that accentuate aging or loss of life span (expressed as minus time) or retard aging (expressed as plus time). These measures are derived directly from human records. They are grouped according to whether they appear to be reversible or permanent. Most of the effects that are not partial measures of the same state are apparently additive, in the few instances that can be tested for this property. (See p. 1107.)

Certain of these circumstances that modify health are partially interrelated, others may be independent of one another. Estimates of effect upon physiologic age may be additive, depending upon the extent to which they are independent. Thus country against city dwelling may be suspected to include the factor estimated as exercise benefit. The lipoprotein test already contains information that can be estimated partially by relative overweightness, and the lipoprotein tests already accounts for a portion of the smoking effect. Familiar inheritance is independently estimated from each ancestor; male against female differences are equally added to city against country effects, and presumably each separate disease sign in the impairment study is additive.

In further support of the additive nature of effects upon health, each morbidity circumstance that can be quantitatively estimated produces an effect proportional to the intensity of the circumstance. Examples of proportional change in mortality risk with morbidity severity are:

(*a*) Overweight: —0.17 year for each percent overweight
(*b*) Smoking: —0.45 year per cigarette used per day
(*c*) Radiation: —5 to 10 —days per r. of whole body radiation
3 cells killed per 1,000 cells per r. (marrow and lymphatic tissue)
4 cells with chromosome breaks per 10,000 cells per r.
1.4 percent increase in lukemia per r.
(*d*) Atherosclerosis, diabetes, nephritis: End effects are proportional to severity of metabolic error
(*e*) Accidents are proportional to exposure risks

A somewhat similar tabulation can be made of an estimation of the cost of industrial and transportation progress in this century in terms of years of life span lost by accident death, distributed to the average individual in the population of the United States (table II). These values are approximately comparable to the preceding values based upon changes in physiologic age. (See p. 1108.)

In about the same way, we can tabulate the effects on life span of radiation received (table III).

---

[12] This estimation of life span lost or gained is in terms of relative physiologic age change. Change in life expectancy may be estimated by determining life expectancy at a given age in terms of a given age+*n* years' change in apparent age. Thus, a person of age 40 has a normal life expectancy of 31.1 years. If his physiologic age is 50 (because of a sum of factors predicting —10 years age over the average), his life expectancy (from life tables) is 22.8 years, or an average loss of life span of 8.3 years. Thus the life expectancy lost in somewhat less than physiologic time lost.

TABLE III.—*Estimation of radiation effect upon health and life span*

Radiation received	Life shortening (in years)	
	If l. r.=−5 days [1]	If l. r.=−10 days [1]
(r.)		
50	−0.7	−1.4
100	−1.4	−2.7
200	−2.7	−5.5
400	−5.5	−11.0

[1] 2 columns are given because of uncertainty whether l. r.=−5 days or −10 days.

Thus it is observed that, although the estimated effect of radiation upon life span is a number worth attention, its magnitude of effect at low accumulated dosage is slight compared with many public health problems. It must be remembered that major problems such as smoking and overweight and fat metabolism are so subtle that they are estimated and established not by clinical methods but rather by statistical (actuarial) researches involving large population samples. The effect of smoking 1 pack of cigarettes per day, for example, appears equivalent in reduction of health and life span to the effect of between 200 and 400 r. of accumulated whole-body radiation. This is several times as great as the 50-r. limit currently recommended for occupational exposure; and 50 r., in turn, is on the order of 10 times as much as the individual would accumulate through fallout. If the life-span loss is estimated as 5 to 10 days per r. of whole-body exposure, the loss due to 50 r. falls within the range of —0.7 year to —1.4 years of life span. This effect is greatly exceeded by the magnitude of the smoking problem; the obesity problem; the problems of atherosclerosis, diabetes, and all the chronic diseases; the benefits of marital status; etc. The effect of 50 r. of whole-body exposure to the general populace can also be viewed as being in the same category of life-span loss as that which results in the population of the United States from use of the automobile. This estimation, however, does not include the problem of the mutation burden in the next generations following such radiation exposure.

SUMMARY OF THE FALLOUT PROBLEMS ON A GLOBAL BASIS

On a global basis, the fallout intensity of radioactive materials is no more than one-millionth of the high-level fallout that occurred by mishap in the vicinity of a thermonuclear explosion in the Marshall Islands in Ooctober 1954. Current estimations made directly in humans throughout 1953–56 place the fallout exposure from strontium 90 as being, on the average; sufficient to produce an irradiation effect of approximately 0.004 r./year to human bones. This is a small quantity of radiation—2 percent of naturally occurring bone radiation—and estimates of effects derived from this additional tissue burden will be correspondingly small compared with other human problems.

At the present time, according to the Libby report (October 1956), there is in the stratosphere about 2.2 megacuries of Sr–90,[13] and a similar quantity of cesium 137.[14] If all the material in the stratosphere (in the fall of 1956) were to descend upon the surface of the earth uniformly, the amount of either Sr–90 or Cs–137 would be about 12 millicuries per square mile. The time of retention by the stratosphere of highly dispersed fission products is on the order of many years. Measurements indicate approximately 10 percent fallout per year and 2.5 percent radioactive decay. As about 25 percent has been added to the stratospheric reservoir of dispersed fission products during the past 2 years, the level in the stratosphere has remained nearly constant over that time. The quantity of Sr–90 in the soil of the United States is somewhat greater than expected from the fallout estimated on an average global basis; in the far west it is

[13] Strontium 90 has a half life of 25 years and decays by emission of a β particle of 0.54 Mev. maximum energy to produce yttrium 90. Yttrium 90 is short lived (half life 65 hours) it decays to the stable zirconium by emission of a β particle having a maximum energy of 2.24 Mev. Because of the short half life of the daughter product and the probable insoluble chemical form of yttrium, the radioactivity of strontium 90 is equivalent to both its own beta decay and that of yttrium 90.

[14] Cesium 137 has a half life of 33 years and decays by β emission (0.52 Mev. maximum energy) with associated γ emission (0.66 Mev. energy.

23 m C of Sr–90 per square mile. This is due to the heavier fallout in the near vicinity of a nuclear exposion.

Strontium 90 distribution to September 1955

	mC/square mile
Worldwide except the United States and Pacific Islands	3. 4[6]
United States, except Utah, Colorado, New Mexico, and bordering regions	4. 9[6] / 12. 5[5]
Utah, Colorado, and New Mexico	20–23

The specific ratio of Sr–90 to normal calcium is a convenient way of expressing the Sr–90 problem.[15] This is because strontium closely follows calcium in chemical behavior. The levels of Sr–90 directly measured in young human bones during the period up to October 1956 are in the vicinity of 0.0038 r/year to the bone. Strontium 90 is deposited preferentially in the bone by a factor of more than 100 over the soft tissues, so that only the bones need be considered with regard to this isotope.

The Libby report estimates, on the basis of a balance between accumulated fallout of Sr–90 into the soil and uptake by cattle and man, that in America the human ratio of Sr–90 to calcium may eventually become 10 to 30 percent of that observed in the topsoil. The report estimates that Sr–90 now held by the stratosphere, in descending to the earth over the next 4 years, will produce a human Sr–90 concentration of from 0.016 to 0.038 r./yr. (0.004 to 0.010 MPC[16]), assuming that no further Sr–90 is added. The range of this expected gain of radiation exposure is equivalent to the extra cosmic radiation exposure experienced by individuals dwelling at altitudes of 5,000 feet (e. g., Denver, Colo.) compared with individuals at sea level. The estimation assumes that there is a selection factor[17] favoring calcium over strontium in uptake from soils into the plant and into the cow and into the human bones, so that 70 to 90 percent of the soil strontium is rejected in favor of calcium.

Both human adults and stillborn babies have similar concentrations of Sr–90 (i. e., similar Sr–90/Ca ratios). This is to be expected, since the developing child draws its calcium from the maternal calcium pool, which is in partial equilibrium with maternal bone. Both these human sources of measured Sr–90/Ca have been placed during 1954 and 1955 at approximately one-sixth of the value for cow's milk; the resultant adult human bone irradiation value for this period is about 0.0019 r. yr. (0.0005 MPC) from the Sr–90 content. Reported values for adults

[15] A convenient concept, established by relating irradiation of bone to bone cancer, is that a maximum permissible concentration (1 MPC) of strontium 90 is equal to 1 μC Sr–90 per 1,000 grams of calcium. The concentration of calcium in the bones is such that 1 MPC can also be expressed as 1 μC Sr–90 per 7,000 grams of bone. The concentrations of radioactive strontium are usually expressed in units of 0.001 MPC; the equivalence is 0.001 MPC $= 1.4 \times 10^{-7}$ μC Sr–90 g of bone, corresponding to 0.0038 r/year.

[16] MPC=maximum permissible concentration.

[17] Harrison et al. have evidence that elemental strontium-to-calcium ratios, compared in food, blood plasma, and bone, are strikingly different; for man they are:

	g Sr/g Ca	Proportional units
Food	17×10^{-4}	7
Plasma	4×10^{-4}	2
Bone	2.5×10^{-4}	1

This is confirmed by Comar in observations using radiostrontium and radiocalcium simultaneously added to the diet. In Comar's observations for milk, the discrimination achieved against strontium in the deposition ratio of Sr/Ca may be less than that for other food sources, in which strontium and calcium may have different chemical binding.

The problem of a protective discrimination for humans against the uptake of the maximum Sr–90/Ca ratio is presented in the Libby report. At this stage of understanding, this apparent reduction of Sr/Ca in bones of humans compared with soil, plants, or animals seems to reside partly in the large calcium pool of the adult cow's body, which constantly dilutes incoming strontium and calcium so that milk, at present, is always intermediate in Sr/Ca ratio between the cow's bones and the forage. Similarly, the human calcium pool dilutes incoming Sr/Ca (largely from milk products) so that human bones at this time always have a lower Sr–90/Ca ratio than cow's milk or cow or calf bones. The content of children's bones is much higher than in adult or stillbirth material. There is some evidence for atomic discrimination between strontium and calcium, but the problem needs further study to determine how much of Sr–90 uptake by bone is lessened at fallout equilibrium. If only dilution operates, with little or no discrimination, humans will develop a higher Sr–90 level than is now expected.

did not exceed 0.004 r. yr. in the sample studied, except for one individual measured at 0.008 r. yr. This is a very small number in terms of radiation effect.

If, in the fallout to be expected, the discrimination against Sr–90 in its course from soil to plant to human bone is by only a factor of 50 percent instead of a factor of 70 percent to 90 percent, Libby's estimate of the future Sr–90 concentration would have to be increased to 0.075 r. yr. (0.020 MPC), based on the present stratospheric and soil burdens. This level of Sr–90 would represent an additional radiation exposure to the bone, equivalent to the additional cosmic radiation experienced by those who dwell at 10,000 feet in this latitude.

Libby has estimated, from soil calcium levels, that if the entire Sr–90 burden reached the soil and humans came into equilibrium with the top 2 inches of average soil, humans would eventually approach a maximum value of 40 $\mu\mu C$ Sr–90/g Ca, or about 0.15 r. yr. of bone irradiation. Such a value would approximately double bone irradiation over natural radiation.

ESTIMATION FROM HUMAN BONE ASSAYS OF FUTURE HUMAN BONE CONCENTRATIONS OF STRONTIUM 90

The uptake of Sr–90 has been directly measured in human bones as a function of age, and of location and time of collection (Libby, (5) Kulp et al.). The following summary conclusions can be drawn from analysis of this information:

1. Strontium 90 content of the bones in human stillbirths is increasing and, on the average, is estimated from Libby as follows:

United States of America	$\mu\mu C$ Sr-90/g. Ca	Percent increase per year
December:		
1953	0.14	
1954	.30	114
1955	.66	120
1956	[1] (1.3)	(100)

[1] Extrapolated.

2. The bones of stillborn humans have a much lower Sr–90 content than those of year-old children. The Sr–90 content of children's bones, which may be averaged from the Libby report, is given in table IV. This table is representative of the Sr–90 concentration observed in children of early ages at two study intervals, namely September 15, 1954, and August 1, 1955, average collection dates. Newborns (stillbirths) have a much lower Sr–90 concentration, because the uterine source of Sr–90/Ca has some intermediate value between dietary Sr–90/Ca and adult tissue-bone Sr–90/Ca. The value for stillbirths, as of January 1955, is 0.31 $\mu\mu C$ Sr–90/g Ca; at this same time, growing children, age 0 to 5 years, are laying down Sr–90 at 2 $\mu\mu C$ Sr–90/g Ca. Thus, the fetal tissues appear to have available to them only 0.31/2=0.16 as much Sr–90 as the growing child. This is a reasonable fraction, considering the lesser relative amount of milk products consumed by the average mother and the fact that her tissue stores of calcium are largely from the prefallout era. The growing child at each interval of growth (i. e., 0 to 1 year, 1 to 2 years, etc.) dilutes the entering Sr–90/Ca by the existing quantity of Sr–90/Ca already present in the body. However, analysis of the increment increase in Sr–90 content shows that children of all ages are consuming and laying down equivalent concentrations of Sr–90/Ca, and that in January 1955, this concentration was approximately 2 $\mu\mu C$ Sr–90/g Ca.

On this date, three sources of milk showed the following ratios:

Radiostrontium content of milk samples, January 1955

	$\mu\mu C$ Sr-90/g Ca
Foreign cheese (5)	2.0
Chicago milk (5)	1.9
New York milk (7)	1.6

Since growing children have milk as their chief source of Sr–90, it is as expected that the value of milk closely approximates the concentration of Sr–90/Ca being deposited in growing bones. These values imply that, should milk remain as it was in January 1955, all children born close to this date

will eventually have in their bones an average concentration of Sr–90 of 2 $\mu\mu$C Sr–90/g Ca.

However, the milk Sr–90/Ca is increasing, and has been increasing since monitoring of milk was begun in 1953. Eisenbud's report [18] gives the following.

TABLE IV.—*Strontium 90 content of cildren's bones (from Libby report)*

Age	Weight		Sr–90 content		Sr–90 content in newly formed bone [1] (corresponding to January 1955)
	Average at measurement	Δ/yr.	Aug. 1, 1954, to Nov. 1, 1954	June 1, 1955, to Oct. 1, 1955	
	kg	*kg*	*$\mu\mu$C Sr-90/g Ca*	*$\mu\mu$C Sr-90/g Ca*	*$\mu\mu$C Sr-90/g Ca*
Birth	3.3		0.25	0.53	
1 year	7.2	3.9	.54	1.16	2.2
2 years	9.6	2.4	.43	.87	2.1
3 years	11.5	1.9	.39	.68	2.2
4 years	13.4	1.9	.35	.54	1.7
5 years	15.1	1.7	.33	.44	1.3
Average					1.9

[1] See the following:

$$\frac{\Delta\ \mu\mu\text{C Sr}^{90}}{\Delta\ \text{g Ca}}=\left[\frac{\text{Sr}^{90}/\text{Ca}_{(t_2)}\times \text{wt}_{(t_2)}-\text{Sr}^{90}/\text{Ca}_{(t_1)}\times \text{wt}_{(t_1)}}{\Delta\ \text{wt}_{(t_2-t_1)}}\right]\times\frac{12.0}{10.5}$$

(The 12.0/10.5 is the correction factor for 10.5-month time interval Sept. 15, 1954, to Aug. 1, 1955.)

Sr–90/Ca content of milk in the New York area

Date:

	$\mu\mu$C *Sr–90/g Ca*
June 1954	1.2
January 1955	1.6
June 1955	2.0
January 1956	2.7
September 1956	5.0

The minimum estimate of future average human burden of Sr–90, then, is that 5 $\mu\mu$C Sr–90/g Ca will be present in the bone. This corresponds to the latest reported value for milk concentration and to the fact that bone acquisition of Sr–90/Ca in growing children is very similar to milk Sr–90/Ca.

A difficult current problem is the estimation of future Sr–90/Ca in milk. The level of Sr–90/Ca in milk is increasing, and, by linear extrapolation, may be expected to raise the Sr–90 concentration in a year's time (by September 1957) to about 7 $\mu\mu$C Sr–90/g Ca. At this date, accumulated fallout of Sr–90, based upon the quantity estimated at the time of the Libby report, may be about 25 percent [6] to 50 percent [5] of the amount initially dispersed in the atmosphere. Since the Libby report was written, other nuclear detonations have occurred, so that it would be very reasonable to assume that fallout; by some 10 years from now, should have increased milk levels significantly. For lack of better information, we may assume a factor of, say, 3 to 5 times as much as September 1957 (allowing for residual hold-up in the atmosphere and for decay of Sr–90). Thus, milk levels and human bone levels by 1967 may be 20 to 35 $\mu\mu$C Sr–90/g Ca.

An additional factor must be considered, which may require that these future estimates be even higher. Cows, in body content of Sr–90/Ca, may be expected to lag several years behind the plant and soil levels. This is because of the large calcium reservoir in their bones and other tissues, and bcause the start of growth to milk-producing stage preceded current time by 4 or more years; moreover, the food consumed by dairy cows is customarily stored for many months before it is eaten. It is difficult to estimate that point in fallout time that corresponds to current milk values; it seems likely, however, that the Sr–90/Ca content of the bones of pasture-fed calves approximates the Sr–90/Ca level that adult cows

[18] Merril Eisenbud, Global Distribution orf Radioactivity From Nuclear Detonations With Special Reference to Strontium 90, Washington Academy of Sciences, fall symposium, November 15, 1956, Washington, D. C.

would secrete in their milk, were they in more rapid equilibrium with fallout. The following table, derived from values averaged from Libby's and Eisenbud's reports, shows that calf bones are approximately 60 percent higher in Sr-90/Ca content than milk. Thus, future estimations of Sr-90 levels should be at least 60 percent higher than the 20 to 35 $\mu\mu$C Sr-90/g Ca estimate, or, say, 30 to 50 $\mu\mu$C/g, in round numbers.

Strontium 90 content of various materials (in $\mu\mu$C/g Ca)

	Mid-1953	Mid-1955	Mid-1956
Milk	1.1	2.1	3.6
Calf bones	1.4	3.5	5.7
Alfalfa (Wisconsin)	6.7	18.0	
Soil (Wisconsin):			
2 to 6 inches depth		9.0	
0 to 2 inches depth		35.0	

It appears that the Sr-90/Ca of cow's milk is a close index of the concentration of strontium in newly acquired human bone. Current milk levels suggest that children's bones in the next decade will approach an average concentration of approximately 50 $\mu\mu$C Sr-90/g Ca. This is in close agreement with the estimation by Libby of a minimum average concentration of Sr-90 of 10 to 40 $\mu\mu$C Sr-90/g Ca. These estimates do not consider local variance in the United States, nor, with respect to future concentrations, the special problem of high-rainfall or low-calcium areas.

The upper value of approximately 40 $\mu\mu$C Sr-90/g Ca has been set by Libby upon the consideration that this is the projected specific concentration ratio when all the fallout is complete and mixed with the average calcium content of 2 inches to topsoil. There does not seem to be a way of independently confirming the upper average limit of radiostrontium concentration from observation of milk or bone. The biological concentrations are increasing rapidly with respect to time, approximately following the level of total accumulated fallout, and 40 $\mu\mu$C Sr-90/g Ca may not truly be a limit.

Whatever the speculation concerning future levels of Sr-90 in humans, we can be certain that current values (1956) represent a low level. If we translate a small dose such as 0.0038 r./year (0.001 MPC) into numbers predicting an increase in leukemia mortality (an estimate may be based upon tentative data that leukemia tendency may be doubled by 50 r. whole-body exposure[19]), an increment of

$$\frac{0.0038 \text{ r./yr.} \times 50 \text{ years mean life span}}{50 \text{ r./tumor doubling}} = 0.004,$$

or 0.4 percent increase in leukemia, is estimated. Since there are only approximately 8,000 cases of leukemia deaths reported in the population of the United States per year (plus 2,000 cases of bone-tumor deaths, which may be similarly affected by radiation), such a radiation burden is equivalent to an increase of 40 cases per year after 50 years' equilibration with this level of fallout. If radiation fallout and uptake of Sr-90 in human bones were to increase by a factor of 10, one could estimate 400 additional cases of bone tumor and leukemia induced per year after a 50-year period, in comparison with 1 million deaths from all causes and 10,000 expected deaths from leukemia and bone tumors. Both above numbers are small in comparison with overall public health problems.

Although there are some sizable uncertainties regarding Sr-90 burdens during the next 10 to 20 years, it seems from the average human values that Sr-90 may increase and become a public health problem if levels should rise to 50 $\mu\mu$ CSr-90/g Ca (equal to about 0.2 r./yr. to bone). There is time—but not much time—for a reevaluation of many unsatisfactorily estimated aspects of this problem, including the extent to which radiation exposure induces leukemia and bone tumors, and more precise estimation of the strontium levels in humans.

[19] This number may be high, since it is based upon whole-body radiation exposure, while induction of leukemia by Sr-90 exposure is the result of direct irradiation of bone and marrow, the specific tissues involved in the leukemia change.

At the reference level of 1 MPC of Sr–90 burden, which is 4 r./yr. to bone, an estimated increase in bone tumors and leukemia is

$$\frac{4\text{ r./yr.}\times 50\text{ years}}{50\text{ r. per doubling of incidence of tumors}},$$

or an approximately fourfold increase in natural expectancy of these neoplasms with respect to the radiation-related component of their origin. This level may be reached by humans as a result of Sr–90 fallout. At some such value, reason argues against further exposure. The 1–MPC value based on radium exposure is consistent with a prediction of a fourfold increase in natural incidence of tumors. It would be difficult to observe a fourfold increase above natural incidence of bone tumors in animal-colony studies with radium, but not at all difficult in large human populations.

In summarizing their opinion for the British Report Cmd 9780, Mayneord and Mitchell write, "It appears however that each unit quantity of radiostrontium absorbed by bone confers a certain probability of bone-tumor formation, the tumor development time perhaps decreasing and the tumor incidence increasing with the dose. On the whole, the experiments seem in favor of a proportionality between the frequency of tumors produced in a given length of time and the amount of radioactive material in the body even at low-dose levels."

The problem in the experimental animal is that the frequency of bone tumor appearance is so slight that statistically significant increases in the frequency are not to be expected as a result of irradiation. The human problem is similar in that osteogenic sarcoma and leukemia are relatively unlikely occurrences, together causing about 1 percent of adult deaths in the United States, so that a small percentage change in incidence caused by radiation could not be distinguished from random fluctuation, and a relatively large fractional increase in the number of these cancers would not appreciably increase the total death rate.

No gross evidence of osteogenic sarcomas has been observed following administration of P–32 (approximately 100 rep to bones) to polycythemia vera patients. However, these patients do have a high incidence of leukemia. This leukemia tendency is probably attributable to both the radiation exposure and the nature of the basic disease of the blood-forming system in these patients.

Special phases of the Sr–90 problem need additional examination:

(*a*) In several areas of the world, Sr–90 concentration exceeds the average world values by more than a factor of 10(4, 5). This excess poses questions as to the origin of the enhanced concentration. To a reasonable extent, it is explained by Libby as calcium deficiency of soils in such areas. Rainfall variation also leads to variation in fallout. It will be useful to know more about these anomalous effects. Current worldwide sampling is perhaps far from representative of the world as a whole, because special effort was made to seek out low-calcium high-rainfall areas.

(*b*) There may be a factor-of-8 difference between Sr–90/Ca concentrations in soil and in humans, resulting from discrimination in favor of calcium (Libby); this must be further studied.

(*c*) Some factor of uncertainty must be allowed for in the prediction of levels today and in the early future of Sr–90 in humans, considering that the most recent of these measures are based on early 1956. These uncertainties may amount to a factor of somewhat more than 10.

(*d*) Although it is unlikely that all these factors would reach their maximum, nevertheless, the total uncertainty in the estimated human burden of Sr–90 throughout the world could mean an upper limit of 10×8×10×Libby's lower estimate of exposure in the near future, 0.02 r./year, which works out to about 15 r./year or 4 MPC. This possibility indicates that the Sr–90 fallout problem urgently calls for further attention.

CESIUM–137 FALLOUT

The Cs–137 problem is quantitatively similar to that of Sr–90. These two fission products are present in the air and in fallout in approximately equivalent quantities (5), and they have similar decay rates. Whereas strontium is a bone seeker, cesium is found in approximately equal quantities throughout the body, though less in bone than in soft tissues. Its distribution roughly approximates that of potassium. Furthermore, cesium is not retained by the body. Thus, the cesium burden at any given time rapidly reaches equilibrium with the rate of fallout, in the potassium pool in plants and animals.

Marley, in the British report (4), writes (p. 124), "The highest body-activity detected so far in the United States is found to be $4 \times 10^{-3} \mu C$. This activity if maintained would produce a total body irradiation of 0.0006 r per year or about one-thirtieth of the dose due to naturally occurring potassium-40 in the body." Since this time in early 1956, the fallout level and fallout rate of Sr-90 have been increased only slightly, so that we may assume that the Cs-137 level in man, which is more reflective of immediate fallout, may have risen by as much as a factor of 2. It should remain nearly at this level, estimated as a maximum of 0.0012 r/year, for an indefinite period.

Cesium-137 body burden at 0.001 r/year is certainly not to be considered an adult hazard. With a linear relation between effect and dosage, 0.001 r/year over a lifetime would be less than 0.1 r, and irreversible accumulative effects of radiation, such as leukemia, might be increased by less than

$$\frac{0.1 \text{ r.}}{50 \text{ r. leukemia-doubling dose}} = 0.002, \text{ or } 0.2 \text{ percent.}$$

Stated in terms of life span lost or of the total tendency toward disease, 0.1 r Cs-137 dose $\times$—10 days of life span per r amounts to 1 day lost from the life span. A loss of 1 day is very small compared with health-modifying factors that are measured in years instead of days. Thus, in comparison with the smoking problem, the long-term effect of Cs-137 is approximately one-forty thousandth as deleterious. Only this extraordinary method of estimation by extrapolation of effect can convince the human reason that there is any such effect at all; even the best statistical procedures could not detect it through study of the most accurate data on the 160 million people in the United States. A 0.2 percent increase in leukemia (which is approximately $0.002 \times 8{,}000$ cases per year) is just 16 additional cases. This 8,000 expected normal incidence can fluctuate by random interplay of chance factors by plus or minus 1 percent, equal to 80 cases per year; thus, 16 cases of increased incidence cannot be detected.

THE LEVEL OF RADIATION EXPOSURE FROM FALLOUT

The total increase in background radiation on a global basis, as a consequence of radioactive fallout, has been very slight. In the preatomic age, natural sources of radiation produced an average radiation exposure of 0.1 to 0.2 r/year. The variation is due to slight geographic differences, to differing radioactive content of earth and buildings, and to the variation of cosmic radiation with altitude. At 5,000 feet above sea level, cosmic-ray intensity (measured by numbers of ionizations produced in matter) is increased to 1.5 times the sea-level intensity of cosmic rays; at 10,000 feet, the cosmic-ray ionization is 3 times that at sea level.

The increased human-tissue irradiation due to fallout and ingestion of radioisotopes is approximately as follows:

	Soft tissue irradiation (r/year)	Bone irradiation (r/year)
1955-56:		
Cs-137	0.0009	<0.0004
Sr-90	0	[1] 0.002 [2] 0.004
Predicted future values:		
Cs-137	0.0012	<0.0066
Sr-90	0	0.04 to 1.5

[1] Adult.
[2] Young.

Table V lists human radiation exposures from a number of sources.

TABLE V.—*Human radiation exposure (r./year)*

A. EXTERNAL EXPOSURE TO WHOLE BODY

Natural radiation exposure		Exposure from fallout from nuclear detonations	
1. Cosmic radiation at—		1. Fallout to earth, October 1952 to September 1956:	
Sea level	0.038	Salt Lake City	0.050
2,000 feet	.043	All other United States cities and other countries	.003
5,000 feet	.056		
10,000 feet	.112		
15,000 feet	.214		
2. Radiation from the earth:			
England	0.04

[4] Possibly the true value is 0.001 or less.

93299°—57—pt. 2——9

The problems of radioactive fallout may also be examined in comparision with other ways of acquiring exposures to radiation (English values for radiological exposure are generally much less than in America (4)). (See table VI.)

Thus, it is possible that, from common use of X-ray-generating devices, the average person in the United States has already begun to accumulate an exposure to radiation effect that is sizable compared with the fallout problem. That no gross evidence of disease has become evident during these past few years of increasing radiation exposure does not disprove the existence of slight average effects of radiation. For example, at current estimation of leukemia induction by radiation, about 20 percent of the relatively rare cases of leukemia (0.5 percent of adult fatalities) may be attributable to natural radiation. There is no difficulty in believing that supplementary radiation resulting from our modern activities may have been responsible for the other 80 percent of known cases of leukemia; the average additional artificial radiation exposure per year would only have had to be 0.8 r. to account for this difference. Considering the generous use of unshielded and unfiltered X-ray equipment in dental offices and shoestores alone, and the lack of public and professional appreciation of need to minimize radiation exposure, it is even reasonable to conjecture that the addition of artificially created radiation exposure to natural irradiation may essentially account for leukemia. Faber has analyzed 828 cases of leukemia registered in Denmark in the period 1950–53 with regard to the amount and type of irradiation each patient received for 20 years prior to development of leukemia. The incidence of previous incidental X-ray or radiation exposure for the chronic lymphatic leukemia cases was 18 percent, for myeloid leukemia, 30 percent, and for acute leukemia, 32 percent. It appears that both acute leukemia and myeloid leukemia can be induced by radiation; and the traceable X-radiation induction may account for a sizable percentage of current cases in Denmark. Faber's information does not rule out that lymphatic leukemia may also be induced by radiation. The analysis of leukemia incidence in followup of three groups of individuals who had had varying exposures to X-rays or other radiation strongly suggests that the radiation induction of leukemia is proportional to the radiation exposure, and that for whole-body radiation exposure the number would be entirely consistent with an estimation that 50 r. doubles the chance of development of leukemia.[30]

TABLE VI.—*Common means of exposure to radium*

Source	Exposure	
	Directed to the specific body region	Scattered to the whole body (dose per use)
Routine chest X-ray [1]	0.05 to 2 r./exposure	
Fluoroscopic examination [2]	10 to 20 r./min	1/200 to 1/1000 of local dose.
Cinefluorography [3]	25 r. per examination	
Dental X-ray [1]	10 to 150 r. per whole-mouth series.	0.01 to 1 r.
Shoestore fluoroscopy [1, 2] shoe-fitting unit	50 to 150 r./min. to feet	1 to 10 r./min.
Radium-dial watch [1] μ C/watch	7. r/yr. to the wrist	0.01 r./year.
Radium and X-ray [1, 2, 3] technicians (throughout the world).		p.1 to p.3 r./week, 5 to 15 r./yr.
AEC maximum permissible dose for 20 years' exposure.		15 r./yr. at 0.3 r./week.
Average accumulated exposure of 10 most highly exposed individuals over 5-year period—U. C. Radiation Laboratory.[4]		0.1 r./week, 5 r./yr.

RADIOIODINE FALLOUT

Of all the problems that we can currently evaluate, the radioiodine fallout problem is disposed of most readily. Radioiodine is produced in thousands of curies by some of the nuclear detonations, and, in falling to the earth's surface, it contaminates grass and is eaten by foraging animals. In its fallout, it is

[30] Court-Brown and Doll, Summary of Leukemia Induction, British Report (4), pp. 84–89.

greatly diluted and does not at any time become a human problem. The herbivorous animal, however, eats large quantities of grass; and in the cow, for example, essentially all the iodine 131 ingested accumulates in the thyroid gland. Over a few days' time, several hundred pounds of grass may be eaten, and all the iodine contained becomes concentrated in the 15 to 30 grams of thyroid tissue. Following nuclear detonations of the last 2 years, the thyroid concentrations of radioactive iodine in pastured cattle reached as high as 0.001 to 0.003 mμC/g (depending upon the quantity of fallout), and the average radiation exposure, as measured over 3 years, was about 1 r./year to the thyroid tissue. This would be of genuine concern to man at similar human burdens of I–131, because it is now known that thyroid tissue is especially sensitive to radiation induction of tumors. However, cattle fed principally in feed lots have only 1/100 (or less) as much I–131 as range-fed cattle. Further careful measurement of fresh human thyroid material has been routinely made during the last 2 years by techniques that are sensitive and reliable for estimation of I–131 content. Direct measurement shows that human thyroid, at any time of high uptake of I–131 by bovine thyroid, has less than 1/5000 of the bovine I–131 content. It is possible that human thyroids had less than 0.0006 mμC/g during the latter part of 1956, when range cattle had 1 to 2 mμC/g. It is certain that the human thyroid exposure during the 1956 period did not exceed 0.001 r./year, and the probable value is 0.00016 r./year or even less. (Interestingly, one human thyroid showed an activity comparable with bovine thyroid content of I–131; the case, when traced to its source, proved to be from a man who had previously been given a small tracer dose of I–131 in the Donner Laboratory. The observed quantity of I–131 was accounted for by the magnitude of the dose, the estimated excretion, and the radioactive decay.)

Up to this time, radioiodine from worldwide fallout is not a problem of concern to humans; and it is not expected that it will become a problem in the future.

SUMMARY

1. This paper reports a broad examination of the levels of radiation exposure incurred from fallout. The discussion is limited to Sr–90, Cs–137, and I–131, the only radioactive isotopes reported to become associated with human environmen in detectable quantities.

2. The worldwide effect of radiation from fallout is now far less than that of naturally occurring radiation from cosmic rays and from radioactive elements normally contained in earth, buildings, and body tissue. The inescapable minimum of natural radiation exposure, for all people, is about 0.1 r./year. The average person at sea level in the United States is probably receiving about 0.16 r./year.

3. During 1954–55 the Sr–90 concentration in human bones (both in adults and in stillborn infants) produced an average exposure to the bones themselves of 0.002 r./year. (Only the bones—not the soft tissues—are exposed to measurable levels of Sr–90 irradiation.) At current fallout trends, the irradiation of human bone by Sr–90 will increase to 0.016 r./year, perhaps even to 0.038 r./year (Libby). The maximum value projected in this discussion is 0.2 r./year. (These are average predictions for the northern hemisphere and for the major population densities of the earth.)

4. Radioiodine (I–131) activity has been measured in humans during periods of likely fallout exposures. Radiation exposure from fallout I–131 is essentially nil for humans.

5. Any analysis of the fallout of radioactive materials on a worldwide basis shows that it does not even remotely approach the threshold for acute radiation effects, which cannot be recognized below 100 r. in a single exposure. Radiation predicted from future fallout is still far less than natural radiation background. Increases in the internal radiation exposure of 0.1 r./year are not meaningful in comparison with acute radiation damage. Attempted comparisons are responsible for most misunderstanding of the fallout hazard to humans.

6. Life-span changes, cancer or leukemia induction, and cell changes appear to be proportional—as are genetic effects of radiation—to radiation exposure. Although these effects are not measurable in any individual exposed to fallout, they can be estimated, in terms of very small risks. The effects are dwarfed

in comparison with the adverse environmental hygienic factors that most persons regard as commonplace. For example:

Factor:	Life-span loss per person (days)
Smoking one pack cigarettes per day	3,000
Being 25 percent overweight	1,300
Having 25 percent elevated lipoproteins	2,500
Living in United States as a driver of an automobile	470
Working in industry (industrial hazard)	100

7. The evidence indicates that Sr–90 may eventually cause a worldwide increase in leukemia, accounting for about 2 percent of all deaths. Compared with the current accident rate, a 2 percent leukemia increase distributed throughout the entire population would be a life-span loss of about 1.0 year per person in the United States; all accidents account for a 2.3-year life-span loss per person, automobile use for 0.87 year. Thus the Sr–90 induction of leukemia is comparable with some of the mechanical mishaps we risk as a partial cost of the "advantages" of our mechanized and energized age.

8. The sum of evidence is that radiation has a deleterious effect upon man's health, but that the effects are extremely small at such slight radiation exposures as are involved in the worldwide fallout. Nevertheless, since radiation probably does affect man's health and progeny—even though minutely for minute exposures—incurring it should be treated as the equivalent of the spending of money or time, and should be allowed only for necessary gainful advantages.

Interpretation of the Atomic Bomb Casualty Commission Report of Physical Growth of Hiroshima Children Exposed to the Atomic Bomb

Hardin B. Jones

Hiroshima children 5 to 19 years old (approximately 4,000, divided into 4 categories—males and females, exposed and unexposed) studied 5 years after exposure to the atom bomb are significantly shorter and lighter in weight than unexposed children, according to the report of Earl L. Reynolds to the Atomic Bomb Casualty Commission. Statistically the effect is slight in either sex, since weight is depressed about 2 percent and height is depressed about 1 percent (the standard error is 0.35 percent for groups of this size). Average individual variation in height or weight is about 12 percent (standard deviation) in Hiroshima children; therefore, the effect on height or weight of average radiation in the exposed group is approximately $\frac{\text{1 to 2 percent}}{\text{12 percent}} \times 100$, or about 10 percent of the effects of factors generally contribuating to lower-than-average individual differences in grows.

The effect of atom bomb exposure upon growth is measurably correlated with distance from the hypocenter of the explosion. The actual relationship observed is slight but significant, the correlation coefficient being about +0.1 for relationship of children's size and distance from the bomb. Since it is very likely that true exposure dose is rather poorly related to distance from the bomb at exposure and correction of this defective information should increase the correlation, the true effect of exposure upon children's growth is probably larger.

An improved estimation of quantitative relationship between exposure dose and growth in these children is possible by using groupings according to initial severity of symptoms, on the hypothesis that indeterminate shielding factors protected those who suffered fewer symptoms than would be expected from the theoretical dose. In comparisons by age and sex groupings, the asymptomatic groups were significantly larger in average physique, whereas the groups with definite irradiation exposure symptoms were significantly smaller. Such comparisons lead to a rough direct estimation of correlation between exposure and suppression of growth. Chi-square values show that the growth depression associated with exposure is significant. When chi-square values are converted to correlation coefficients, the result is equivalent to a correlation of approximately —0.4, indicating that the true relationship between irradiation exposure and growth, in doses sufficient to produce acute effects, may be larger than the above estimate; the square of the correlation coefficient indicates that 16 percent of the observed difference in growth is probably due to the effects of irradiation. Roughly estimated, the growth-depressant effect in humans should be equal to:

$$\frac{\text{growth change}}{\text{roentgen exposure}} = \left\{\begin{matrix}\text{correlation coefficient}\\ \text{of growth vs. exposure}\end{matrix}\right\} \times \frac{\text{standard deviation of growth}}{\text{standard deviation of radiation exposure}}$$

as derived from the regression equation. The computed value in this case is:

$-0.4 \times \frac{\text{10 percent}}{\text{80 r.}} = -0.05$ percent per roentgen, all values being rough approximations.

The association observed between size and radiation exposure in Hiroshima is strikingly similar to that observed by Russell and Russell when mice were exposed to varying single doses of X-rays at 11.5 days after conception. Size of mice at birth decreased proportionally to radiation exposure from 100 r. to 400 r. The estimated effect upon embryonic growth per roentgen is 0.25 percent depression of size per r. It is noted that those children in Reynolds' study who were exposed in utero have twice the effect of decreased size seen in children exposed after birth; however, since the Reynolds study considered size 5 years after exposure rather than size differences at birth, as in the Russell study, the relative size difference at birth may have been even greater. Although the number of children irradiated before birth was too small to make the difference statistically significant, it is interesting to note that only a small correction factor would make the Hiroshima overall growth-depression ratio of 0.05 percent per roentgen comparable to the embryonic growth-depression ratio of 0.25 percent per roentgen observed in mice. These studies suggest that radiation effect upon both young mice and humans is the same with regard to suppression of growth.

Representative HOLIFIELD. Now I suggest that we have a discussion. We have certainly had a heavy diet today of philosophy on genetics and facts presented, and theories. I am sure now we can probably focus on some of the points we think should be focused on at this time. I am going to ask Mr. Hollister to lead off with some questions.

DISCUSSION BY DRS. JAMES F. CROW, BENTLEY GLASS, A. H. STURTEVANT, HERMANN J. MULLER, W. L. RUSSELL, AUSTIN BRUES, AND HARDIN JONES

Mr. HOLLISTER. The first question, to Dr. Glass. Do we know specifically of any mutations in man that are radiation caused?

Dr. GLASS. No, you can't identify the individual mutations as being radiation caused or as having occurred spontaneously. The same kinds of mutations can occur through the action of radiation as may occur spontaneously. So you can't identify the particular mutations. There is aways a probability that even if the exposed person—the parent of the mutant person—received radiation, still the mutation might have occurred anyway. All we can go by is the increase in the frequency of mutations, which is thought to occur with a particular increase in dose.

Mr. HOLLISTER. So the radiation mutations produced in man or in any other organism are indistinguishable by kind.

Dr. GLASS. Exactly.

Mr. HOLLISTER. From any other sort of mutations.

Dr. GLASS. If we looked at the chromosomes we might find that a larger proportion of the radiation induced ones were visible losses, as has been brought out today. But just judging from the ordinary clinical symptoms, no, you could not distinguish them in kind from the spontaneous ones.

Representative HOLIFIELD. Are there any comments, or are you in general agreement? I see by your nodding that you are in general agreement.

Mr. HOLLISTER. I would like to ask, Dr. Muller, if you know of any mechanism seriously proposed that would predict a nonlinear effect for the mutation dose relationship.

Dr. MULLER. At high doses; yes. For what we call chromosome aberrations, but not for what we call gene mutations or point mutations.

Dr. Russell referred to a result of his and we, at our laboratory, obtained a similar one in flies, in which there was a less than linear apparent effect at very high doses, owing, as we judged, to the fact that the cells that had been worse hit were killed off more so that we lost the cases. But I do not see any way of getting a fundamentally nonlinear effect, especially at low doses. If the process takes place in any way like what we think it does, that is.

Representative HOLIFIELD. If any member of the panel wishes to comment, if you will raise your hand, I will recognize you. Dr. Russell.

Dr. RUSSELL. I should like to add to that that I think the possibility does still exist, if there is killing of cells at low doses. That is, down to a level at which cells are killed I think the possibility of departure from linearity might still exist. This level may be lower than we might tend to think from experiments on sperm. The spermatogonia seem to be sensitive.

Dr. MULLER. Might I add one word to that? If that is true, then it would work the other way from the way the people argue who believe in a threshold, because it would mean a relatively greater effect at low doses.

Dr. RUSSELL. Yes. I tried to bring this out, that it would be an increase in the effect, rather than less. But I do not think departure from linearity would be expected at such low levels as 0.1 roentgens, for I don't think there would be enough killing of cells at this dose level to make any difference. This would perhaps apply at the 10-roentgen level or something of this order. Down at the very low doses I would agree 100 percent with Dr. Muller that linearity would be expected.

Representative HOLIFIELD. Dr. Jones.

Dr. JONES. It is certainly true that several ionization events may be necessary for critical change within the cells. The ravages that can take place in the cell with time are so similar to radiation-induced events that even though one ionization occurs and several are needed, perhaps the preceding natural aging events have made the internal climate such that one ionization could produce that change.

In this sense we perhaps have a further reason for accepting the hypothesis of a proportional change down to very, very small doses. Of course, at these small doses we have very small effects.

Dr. RUSSELL. Could I add one more point to this? My point is that at the very low doses you would still expect linearity, but the slope of the line at these low doses might be steeper than would be predicted from our present data at the 300 and 600 r. points.

The question is, Have we measured the full effect at the present time? We think we need to measure the mutation rate at lower doses to be sure.

Representative HOLIFIELD. Thank you.

Mr. HOLLISTER. I would like to ask if it is not true that you as geneticists—when you draw a line between a good and a bad muta-

tion—do this almost entirely on the basis of how the mutation affects reproduction. Who would like to answer that. Dr. Crow?

Dr. CROW. From the standpoint of some theoretical computations that are made in assessing damage in the long-time future, this kind of an assumption is made. But in general, although we realize that most harmful mutations have some harmful effect on survival or reproduction, I think most of us—probably all of us—would be agreed that this is not really the point which as humans we are interested in. We are interested in the pain, disease, misery, all of which are associated with the reduction in survival value.

Mr. HOLLISTER. In other words, it is possible you could get into a situation, for example, where by process of continued mutation and selection, you could achieve a population that would reproduce very prolifically, but would have all sorts of other defects, that is, susceptibility to diseases and shortened life span and so on.

If we apply this criteria of good and bad mutation, you could do this?

Dr. CROW. As a very remote theoretical possibility. I don't think that is a likely possibility at all.

Mr. HOLLISTER. Dr. Crow, another question for you. This is the question of numbers of individuals limiting in the quantitative studies of natural mutative rates either in man or other organisms. Is the size of the population that you have to work with a limiting consideration in the kinds of experiment that you can perform or the kinds of data you can obtain?

Dr. CROW. In the study of human populations?

Mr. HOLLISTER. Either in humans, fruitflies, or mice.

Dr. CROW. I would say the numbers are the principal limiting factor. If one studies humans one cannot make experimental matings and that is serious. The organisms that are preferred for research purposes are those that you can grow cheaply and in large numbers, and that is why the fruitfly has been used.

Is that the point of your question? I am not quite sure.

Mr. HOLLISTER. My understanding is that you had postulated somewhere that there was some size or some number of individuals, perhaps a million or perhaps 10 million, that was a practical maximum size that an experimenter could work with.

Dr. CROW. I think you are confusing me with the U. N. committee. I cannot think of the man's name. Yes, Dr. Appleyard.

Mr. HOLLISTER. That is possible.

Dr. CROW. I think these are statements from Appleyard who has done some computations on the size of population that would have to be studied in order to detect differences of a certain small magnitude.

Mr. HOLLISTER. Is it not true that in some of these studies he has concluded that the populations have to be enormous?

Dr. CROW. That is correct. One can reach those conclusions even before seeing his figures.

Dr. MULLER. Could I interpose something since we mentioned the U. N. committee? I received information from someone in the audience in regard to a question that was raised or that I raised during my talk about the composition of the U. N. Scientific Committee. I stated that Dubinin had been scheduled to appear from Russia. I got information that he did not show up. Also, that he had not been

scheduled to be a delegate, but an adviser or consultant. Also, that at the most recent meeting there were various advisers present from other countries who were geneticists, not delegates, however. The geneticists who were delegates were confined to those I listed. Even though most of the discussion was done by the consultants rather than the delegates, it is an unfortunate situation if geneticists are not actual delegates, because although they were evidently given free rein during the discussions on the effects on posterity, nevertheless, as I indicated before, the effects on the exposed generation itself are also very important, and are very possibly closely related to the genetic subjects. Therefore, the committee should have geneticists to discuss those effects also.

Representative HOLIFIELD. Without objection, the record will be corrected.

Dr. MULLER. Yes, sir; it should be corrected. Our country had two good geneticists as consultants.

Mr. HOLLISTER. Dr. Muller, do you suppose that something analogous to the uncertainty principle in physics could exist in genetics with regard to this threshold question? For example, presumably we have to have an effect, tested in a certain number of cells. Leukemia, bone tumor, these have to involve more than one cell for us to observe. If this is true, does not this of itself indicate a possible threshold when in fact there might not be one. That is, we cannot observe a leukemia in 1 cell, can we, or a bone tumor involving 1 cell? Presumably it involves many cells.

Dr. MULLER. If the individual is unlucky enough by reason of the cell being lucky enough, then the one cell that became leukemic could give the individual leukemia.

Mr. HOLLISTER. But you would not know this until it involved more than one cell?

Dr. MULLER. No. There could be a mutation in one cell if our conception is right.

Mr. HOLLISTER. You would not know this experimentally?

Dr. MULLER. You would know it experimentally if that cell was in position in which it could express the tendency given to it by the mutation to divide or to reproduce or multiply in an uncontrolled manner. After a while it would crowd out the other cells and the person's blood would be full of these white cells, and he would have leukemia.

Mr. HOLLISTER. The thing that you would measure would be the presence of leukemia in the person after some of the multiplication had occurred.

Dr. MULLER. That is right.

Mr. HOLLISTER. So you would not know he had leukemia until it showed up as a result of many cells being pathologic?

Dr. MULLER. I think the question is on the same basis as all other genetic questions. All you get is a more or less random sample. You have to judge by that sample. That is why you need large statistics.

Representative HOLIFIELD. Dr. Glass has something to say on that.

Dr. GLASS. May I speak to that question, too? The more we press back into the knowledge of how the genes produce their effects, the more possible it becomes to detect the nature of those effects in individual cells. Thus even in a tissue culture of human skin epithelial

cells, if a mutation occurred in the one gene that we know of that controls the production of pigment, and changed it to an albino type, you would not have to have a thousand cells or a whole individual to know that mutation had occurred. You could spot it in that one cell.

If we knew enough about the biochemistry of different cells and enzymes, we could easily detect this in single cells.

Senator ANDERSON. Dr. Crow, do you agree with that? It looked as if you did not.

Dr. CROW. Let me get into this act, too. Back to what I think maybe you have in mind. At the present time we can demonstrate a linear effect perhaps down to 25 r. We could do a very large experiment and perhaps demonstrate a linear effect down to 10 r. We could do an enormously large experiment and demonstrate it down to 5 r. One cannot continue indefinitely. If that is what you mean by an uncertainty principle, I think there is something here. One cannot do a large enough experiment to demonstrate linearity down to an arbitrarily low value. Having said that, I would like to say that about this time we start relying on purely physical considerations of the kind that other people such as Dr. Pollard have been mentioning.

Mr. HOLLISTER. How about some of the testimony that Dr. Brues gave, which I am not sure I understood perfectly, and do not have in front of me—and if he is here, he might want to comment himself—to the effect that to cause cancer in body cells more than one cell would have to be affected by a dose of radiation before this effect would occur.

This might imply a threshold, although in fact a threshold might not exist.

Representative HOLIFIELD. Dr. Brues, have you been correctly quoted? Will you come forward? Pull up a chair and defend yourself.

Dr. BRUES. Was the question addressed to me?

Mr. HOLLISTER. I think you can help us first to make sure I paraphrased what I thought you said correctly.

Dr. BRUES. I shall in that case rephrase it to say this: I should not necessarily assume that a somatic mutation would be the basis of cancer a priori. But if it is, it still might be a little more complicated than the genetic situation, where just one cell is involved. I can think of at least two different ways in which that might occur, but I shall not take the time to go into them.

Mr. HOLLISTER. But these complications that you speak of involve the notion that more than one cell would have to be affected by the radiation; is that correct?

Dr. BRUES. That would be correct, yes. This is not proven or disproven, but it is a suggestion which I think is as likely as the other one which has been made, rather categorically.

Mr. RAMEY. Do the complications make for the threshold, then?

Dr. BRUES. I beg pardon?

Mr. RAMEY. Do the complications arising mean that you have to have more dose before you would get some sort of threshold effect?

Dr. BRUES. Yes. I think the suggestion I made rather specifically, and this was based on many things which have been observed in cancer pathology, rightly or wrongly, is the fact that cancer rather tends to arise in a tissue which has been generally disarranged. As for a general disarrangement or disturbance of the blood vessel supply of the tissue, this, I think, is not linear with radiation dose, but

like the erythema produced by irradiation on the skin, the old method of measuring dose, this appears to have some sort of threshold. If that is necessary as well as something else that radiation does, then we will not have a linear response. That is the point I made.

Representative HOLIFIELD. Is there any comment on that? Observing no hands raised, we will go to the next question.

Mr. HOLLISTER. Dr. Crow, do you know if experimentally, a population has ever been destroyed genetically?

Dr. CROW. I cannot think of an example. You mean by accumulating so large a number of mutations that ultimately it was killed off?

Mr. HOLLISTER. Yes.

Dr. CROW. Dr. Russell has reminded me of an example. One of Dr. Bruce Wallace's populations died out presumably as a consequence of very heavy radiation. Is the theoretical point here whether it is possible to induce a large enough number of mutations to kill off posterity without killing off the first generation?

Mr. HOLLISTER. Presumably this experiment proves it is possible.

Representative HOLIFIELD. I think we have time for one more question. We will allow each one of you, regardless of the time element, to comment on this. Are conclusions in the field of genetics being arrived at too far in advance of the data?

Dr. STURTEVANT. It seems to me, sir, that we have to draw some conclusions. We have to do something, because not doing something is equivalent to doing nothing. We therefore have to proceed on the basis of the best information we have. This is a common enough human experience; it happens to all of us every day. We have to reach decisions as to what to do or not to do without all the information we should like to have. I don't think that the situation here is any different from that which is usual. We have to proceed on the basis of the best information we can lay hands on.

Representative COLE. You concur with Dr. Crow when he said it is better to guess wrong than not to guess at all?

Dr. STURTEVANT. I think it is not only better to; it is necessary to. You have to make some kind of guess in order to live at all in this world.

Representative HOLIFIELD. Would there be any other comment on that?

Dr. JONES. I think the same thing applies to the question of life span effects. Here we simply do not know how life span effects operate in the small-dose range. We may be a long time in finding out information that applies directly in the small-dose range. In the absence of that, we have to make some estimate of the effect. If we relate this problem to fallout, we may estimate fallout to be now about 2 percent of natural radiation. Natural radiation is estimated to cause a life span loss of 25 to 50 days, if we live as long as 70 years. So the effect of fallout is only about 1 day or half a day on this basis, if we assume proportionality. This loss is extremely small but may be worth keeping in mind, even though it may be as small as one twenty-five thousandth of man's life span.

Dr. RUSSELL. I should like to make two comments on this. I think the geneticists on the National Academy committee have faced up to this problem, and in some sense should be complimented on this. I am a member of the committee, so I do not want to compliment myself, but the others. Most of them were experimental scientists and

they were very reluctant to come out with figures based on what they would consider, in some respects, inadequate evidence. However, it was necessary to face up to drawing a conclusion.

I don't think anyone should be reprimanded for drawing a conclusion when a conclusion was requested.

Representative HOLIFIELD. I certainly do not want you to think that this committee is reprimanding.

Dr. RUSSELL. No. Other people have.

Representative HOLIFIELD. It is very salutary that you brought this out. We believe it is in line with your scientific integrity to point out danger signs, whether you are sure how great they are or how many.

Dr. RUSSELL. I did not mean to apply my remark to this committee. I believe geneticists have been blamed for making too definite statements based on the evidence, perhaps mostly by medical specialists.

The other point I have is that we perhaps know more about this genetic hazard than we did about many other hazards we have experienced in the past. Many hazards man has been encountering were not known to be dangerous until many humans died from them. For example, many industrial poisons and even radium in the first place. I think the genetic hazard represents a situation where we know in advance a good deal more about it than we have done for some other things, including, I might say, some medical treatments. Some of these have been found to be hazardous only after several people have suffered from them.

Representative HOLIFIELD. Of course, the magnitude of the threat of nuclear radiation from war is the compelling factor in this matter.

Dr. RUSSELL. Yes.

Representative HOLIFIELD. Dr. Crow, I am sure you want to say something.

Dr. CROW. I agree heartily with the two people who have spoken.

Dr. GLASS. I agree, but I would like to add just one very brief comment. We know there is a genetics hazard. We don't know the exact amount of that hazard. We think that it is better to overestimate it than to underestimate it, and play safe, than to underestimate it and reap irreparable damage.

Representative HOLIFIELD. Mr. Ramey has a question, I understand.

Mr. RAMEY. I believe most of you gentlemen sat in on yesterday's discussion of the pathological or somatic effects. As biologists rather than geneticists, do you think that this linear effect that was brought out today for genetics applies in the somatic pathological field?

Representative HOLIFIELD. Who would be so bold as to answer that?

Dr. CROW. I will be so bold as to make an answer, but it will not be very definite. I believe most geneticists are convinced that at least some of the somatic effects of radiation are of a linear nonthreshold sort. I don't think anybody would be so dogmatic as to state that all such effects are or even what the fraction is.

Representative HOLIFIELD. Dr. Muller, what do you think about that? Would you have any opinion on that?

Dr. MULLER. My opinion is, as I said before, that the most important effects, those from which the human race when exposed to radiation suffers by far the most damage, and that is the shortening of

life effect, and probably leukemia and some related things, are in all probability linear without a threshold.

Might I also say with regard to the other question of whether we are going too far beyond the evidence, that it was not, of course, possible in these discussions to present the details of the evidence, and the reasoning involved, but that the estimates that were presented as what we regarded as probable were not in any sense guesses or speculations, but arrived at as a result of an enormous amount of work and calculations. Not only that, but that they were arrived at by more than one method. There was a totally different method used recently by a number of geneticists in arriving at the frequency of mutations in man. It was remarkable that at the end it was in very good agreement with the estimate reached by the first method that we had used.

I would make this qualification only of what Dr. Glass said, that we were not trying in the main to show the maximum effect. I would regard the preferred estimates as minimum estimates.

Senator ANDERSON. My question was not too serious an inquiry. I was just wondering if geneticists had a union, guild or gang, or something that teaches you to hang together? This is not only the most agreeable group of seven scientists, but certainly the most agreed group I have seen. I commend you of the fact that you have been able to hang together as long as you have through a rather long day.

Dr. STURTEVANT. I would like to say that I think it would have been very difficult to get together a group that would have disagreed with most of what has been said here among practicing geneticists.

Dr. MULLER. Might I take the occasion to thank the members of the committee on behalf of all of us for their having put on these hearings on this subject.

Representative COLE. Mr. Chairman, I am not sure that the question can be answered, but at least I am curious enough about it to pose the question.

Are there any other firm conclusions that can be reached based on data and experience with respect to the danger or hazard of radiation other than the one that was just voiced by Dr. Glass, that it does constitute a hazard? I am directing the question at all of them and I prefaced it by saying I was not sure it could be answered, but I was going to ask it anyway.

Dr. CROW. I find it hard to answer, Mr. Cole, because of the difficulty of deciding what we really mean by firm in a case like this. I think the conclusion that any effect of radiation is harmful is about as firm as a scientific conclusion ever is. Of course, the quantitative figures are much less firm.

Representative HOLIFIELD. From the field of physiology?

Dr. JONES. I would echo Dr. Crow's opinion that it looks as though we can definitely say that some effects do occur, and at very small dosages they are undoubtedly small effects. But they seem nevertheless to be effects, and we cannot say with certainty what the relative orders of magnitude of these effects are. I don't think there is any reason to be more concerned than to try to get better information as soon as possible. There is no public hazard at the moment compared to usual concepts of public hazard. We certainly do owe it to ourselves to find out what these effects are.

Representative HOLIFIELD. On behalf of the committee, gentlemen, I wish to express our collective thanks for this participation in this set of hearings. I am sure they will be read by a great many thousands of people with great interest. Your audience will be large. I think these hearings will be the year's best seller.

Tomorrow we will have Dr. William B. Looney as the leadoff witness, followed by Dr. Libby, Dr. Ralph Lapp, and Dr. Walter Selove, in the Senate caucus room at 10 o'clock.

(Thereupon at 5:10 p. m., Tuesday, June 4, 1957, a recess was taken until Wednesday, June 5, 1957, at 10 a. m., in the Senate caucus room.)

THE NATURE OF RADIOACTIVE FALLOUT AND ITS EFFECTS ON MAN

WEDNESDAY, JUNE 5, 1957

CONGRESS OF THE UNITED STATES,
SPECIAL SUBCOMMITTEE ON RADIATION OF THE
JOINT COMMITTEE ON ATOMIC ENERGY,
Washington, D. C.

The special subcommittee met, pursuant to recess, at 10:05 a. m., in the caucus room, Senate Office Building, Hon. Chet Holifield, chairman of the subcommittee, presiding.

Present: Representatives Holifield, Durham (chairman of the Joint Committee), Price, Cole, Van Zandt; Senators Anderson, Hickenlooper, and Bricker.

Also present: Professional staff members: James T. Ramey, executive director; George E. Brown, Jr., Hal Hollister, staff technical adviser, and Paul C. Tompkins, consultant.

Representative HOLIFIELD. The committee will be in order.

The subcommittee will continue its hearings on the effects of radiation on man, and today we will take a step back toward the pathology section of our witnesses. Our witness this morning is Dr. William B. Looney from the John Collins Warren Laboratories of the Huntington Memorial Hospital of Harvard University, Massachusetts General Hospital, who has been for the past 7 years conducting experiments and partaking in clinical work directly with patients who have had radiation damage. We should have had Dr. Looney on 2 days ago when we had the pathology section, but we could not fit him into the program because of the time limitation. We are mighty happy to have him with us this morning.

I notice you have quite an extensive statement here, and it is your purpose to submit this for the record, I understand, and to discuss the highlights of your statement.

Dr. LOONEY. That is correct, sir.

Representative HOLIFIELD. You may proceed, Doctor.

STATEMENT OF DR. WILLIAM B. LOONEY, MASSACHUSETTS GENERAL HOSPITAL [1]

Dr. LOONEY. Mr. Chairman and members of the committee, first, I should like to express my appreciation for the opportunity to

[1] Date and place of birth: March 18, 1922, South Clinchfield, Va. Education: Bachelor of science, Emory and Henry College, 1944; United States Naval Academy, 1941–44; doctor of medicine, Medical College of Virginia, 1948; internship, Presbyterian Hospital, Chicago, 1948–49; assistant residency, internal medicine, 1949–50; AEC postdoctoral research fellow in medical scence, National Research Council, Argonne National Laboratory, 1950–52. Work history: Assistant in medicine, University of Chicago, 1950–52; Radioisotope Laboratory, United States Naval Hospital, Bethesda, 1952–55; Officer in Charge of Radioisotope Technicians School, National Naval Medical Center, Bethesda, 1953–55; subcommittee on radiobiology, National Research Council, 1953–55; Consultant to Egyptian AEC, Cairo, Egypt, 1954–; specialist, Public Health Service Research, fellow of National Cancer Institute, 1955–; clinical and research fellow, Massachusetts General Hospital, 1955–; visiting fellow in physics, MIT, 1955–; consultant in radiation protection to Surgeon General, Department of the Navy, 1957–. (Submitted by witness.)

present this information to the Joint Committee on Atomic Energy.

As was just previously mentioned, my studies primarily have been on the effect of radiation in man, and the importance of the information to be presented this morning on the effect of radiation in man by radium is related to the fact that both radium and strontium are deposited in the skeleton similar to calcium. We have a considerable amount of information about the effects of radium in man; however, we do not on strontium. Since both strontium and radium act similarly to calcium, having the knowledge of radium, we can make estimates of the effects of strontium on man by our knowledge and factual data of the effects of radium on man.

I should like to confine my testimony primarily to the available knowledge we have on the effects of radium in man, and then at the end of the statement, based on the estimates from man, make some estimates as to the radiation dose from strontium necessary to produce similar changes in man over a 70-year period.

Man is constantly confronted with toxic agents in his environment which, if present in sufficient quantities, may produce temporary or lasting changes. By the accumulation of clinical and experimental information about the quantity of these toxic agents which produce minimal changes, safety measures are established. The present maximum permissible concentrations for radio elements in use today are based primarily on the results of clinical and investigative studies made over the past half century.

The principal sources of material for the study of the effects of internally deposited radioactive materials in man have been individuals who were employed in the luminous-dial industry, and persons who received radium for medical purposes. Radium salts had been given orally and intravenously for hypertension, arthritis, anemia, and other medical disorders from about 1915 to 1930. The painting of watch dials with luminous materials containing radium, mesothorium, and radiothorium started in this country in about 1914.

Adequate safety measures were not taken until about 1925–27, following the deaths from bone tumors, anemia, and crippling bone lesions, or all three, which occurred in some of these workers.

The first report in regard to the maximum permissible concentration, which I shall refer to as MPC, for radium was made by the National Bureau of Standards in 1941.

Senator HICKENLOOPER. I hate to interrupt you, Dr. Looney, unless you are willing to be interrupted in your statement.

Dr. LOONEY. That is perfectly all right.

Senator HICKENLOOPER. I notice the statement about the safety measures taken in 1925–27, following the deaths from bone tumors, anemia, and crippling bone lesions, which occurred in some of these workers. Do you comment later on the fact of whether or not all of the workers who received substantially the same dosage had the same results?

Dr. LOONEY. Yes, sir; this will be the context of the report.

Representative VAN ZANDT. Dr. Looney, when radium was first used, was there the same concern regarding the safety factor as there is today for radiation?

Dr. LOONEY. Well, this is a very fascinating history. The initial use of radium medically was based on the finding that radon, which is the first daughter produced by radium, was found in the waters of

the health springs in Europe, and a few biological experiments were done to show that radon or radium had beneficial effects. It was first believed that radiation had primarily a beneficial effect. As a result of the biological experiments and the finding of radon in the health springs, numerous people were treated. Historically, we now have the spectrum shifting from one side to the other.

Representative VAN ZANDT. One more question.

Dr. LOONEY. Yes.

Representative VAN ZANDT. I would like to ask about X-rays. Are you familiar with the development of X-ray from the time it was first used and was concern shown for the safety factor?

Dr. LOONEY. I think Dr. Taylor, who is in the audience here, would be certainly much more competent to comment on the general history. I think he is far more familiar with the overall details.

I will say, though, that certainly throughout the history of the uses of radiation, there certainly has been concern about its deleterious effect.

Representative VAN ZANDT. Thank you.

Dr. LOONEY. To go back to the report, the first report in regard to the maximum permissible concentration for radium was made by the National Bureau of Standards in 1941. Seven individuals having from 0.02 and 0.5 micrograms of radium in their bodies from 7 to 25 years had no noted changes referable to the deposition of radioactive materials. However, death had occurred in patients having as little as 1.2 micrograms of radium. The maximum permissible level of body burden for the amount of radium was established at that time as one-tenth microgram of radium. This was after the initial rapid elimination of radium from the body.

If radium is taken in, almost all of it is eliminated, but the fraction remaining in the bone is eliminated rather slowly. So the maximum permissible concentration for radium was set in 1941 at one-tenth microgram.

There have been two large studies, one made at the Argonne National Laboratory in Chicago, with which I was associated, primarily as coordinator in the evaluation of the clinical aspects with biophysical effects of the investigation. The other was made at the John Collins Warren Laboratories of the Huntington Memorial Hospital of Harvard University, Massachusetts General Hospital, Boston, and the Massachusetts Institute of Technology. These studies are continuing, and I have in the acknowledgments at the end made note of the people involved in these studies.

I would like to emphasize this was a very large study in which I was primarily interested in the clinical aspects, and I shall incorporate in the report the acknowledgment of the large group of people participating in these two studies.

This report is primarily a summary of these two recent investigations of people at or near the present maximum permissible concentration of radium.

Of the 78 patients that have been examined, the mean age of the luminous dial workers was about 21 years, and the mean age of the patients was about 34 years when they received radium. The average time of retention for both groups has been about 25 years with a

range of about 10 to 35 years. The average of these people in 1951 was about 50 years.

To summarize, we have information on people beginning about 15 to 20 years of age, and the major part of these patients have had radium in their bodies for 25 years. Many of these people are in the older age group, although the majority of the people are 50 or 60 years of age. We would like to have for a more complete picture additional information of people in the older age groups, and also people in the younger age groups. We have in the middle of the life span more information, but at either end the information diminishes.

Representative HOLIFIELD. Is there any information that the younger age group, with the same dose, is affected more deleteriously than the older age group?

Dr. LOONEY. Comparison of the effects of skeletal radiation in the unselected luminous dial workers and patients who received radium medically was made. It is not possible to draw conclusions on the present information in these two groups of patients. However, based on the available clinical information one might consider that the luminous dial workers were less affected after beginning employment at ages 15 to 20 years, than the patients who received radium medically in the 1930's.

Representative HOLIFIELD. Is that on comparative doses?

Dr. LOONEY. On comparative doses, yes, sir. As I say, I think this data is inconclusive. This is just based on the information we have available at present in man.

Senator ANDERSON. Do luminous dial workers go to work at 15?

Dr. LOONEY. Fifteen to twenty years of age; yes. Some of them started at 14 and 15. This was in 1915.

Representative HOLIFIELD. And they absorbed this radium, as I understand, by putting the tip of the brush in their mouths to point up the brush in order to paint the numerals on the watches. Was that the way they received it mostly?

Dr. LOONEY. I think this, plus the fact there was radium in the atmosphere and they inhaled it. There were no known effects at that time. In 1924 a dentist discovered destruction of the mandible of some of these people. This established the fact that the ingestion and inhalation of radium produced deleterious effects in man. This very tragic experience is the foundation upon which some of the maximum permissible concentrations of the most important radioelements in use today are based.

There is one other point I think should be brought out in regard to these patients. Ten of these fifty radium patients, and sixteen of the luminous dial workers were selected because of symptoms. In other words, they were discovered because they were having trouble. It is apparent that, if we had a thousand people and we saw only the people who were having difficulty, we would have a biased or selected group of people from the population of radium patients, and luminous dial workers. About one-third of these people were found because they had symptoms. This would tend for one to overemphasize the effect of ardioactive materials based on the present information. This is something the committee should keep in mind.

Thirteen of these seventy-eight patients having between one-hundredth and four-tenths micrograms of radium had no changes attributable to the effects of radium, with two exceptions. One patient

having 0.15 microgram of radium had minor areas of decreased density demonstrated roentgenographically in his teeth. These are minor changes; however, this patient was discovered because of the changes. These findings are characteristic of the dental changes in people we have seen with more radium in their body. The other patient was an 83-year-old woman who had very severe arthritis, was incapacitated, and had minor changes in her skeleton. Old age, plus the incapacity, might have contributed to the changes.

Sixty-five patients had between 0.5 and 23 micrograms of radium. All of these patients had either skeletal changes or symptoms attributable to radium, or both, which we could reasonably attribute to radium, with 3 exceptions; these people had between five-tenths and 1 microgram of radium. We should keep in mind the one-tenth microgram as the present MPC for radium, then we can mentally refer to the changes.

These patients began to have difficulty with about 10 times the amount of radium greater than the maximum permissible concentration.

Now I would like to go into the mechanism of deposition of radium in the skeleton, the pathological changes seen, and then relate these pathological changes to the amount of radium in the body. Radium is deposited in small areas of high concentration, so that we have an irregularity of deposition. This is an important factor to take into consideration, because in the last analysis we are interested in what happens in certain areas. If radium is concentrated in the area of bone tumor formation, then we are not as interested in the average value of total bone, as we are interested in these areas of concentration.

Analyses of samples of bone from some of these people have been made. In samples taken from different bones and from several parts, the same bones, we have found that these concentrations vary as much as by a factor of 10, and maybe greater. When we talk of average values of one-tenth microgram, we must realize that these people have areas of concentration which may be much greater than that. This has to enter into the consideration of the MPC of radium as well as strontium.

If you will go back to figure 2 at the end of my statement, there is an autoradiograph which shows how the radium is deposited in one of the bones. It is the picture here [indicating], showing the actual radium deposition in the bone. You will see that the dark areas represent areas of radium. (See p. 1176.)

In considering the effects of radium, you must consider the effect in the small areas of concentration in relation to the pathological changes.

Now, the changes that have been shown to develop in these people are areas of abnormal bone formation, which occur usually at the ends of the bone. When an X-ray is taken they show up as areas of increased density. The effect of radium causes abnormal bone to be produced, and it is generally considered that tumors develop in and around these areas of abnormal bone formation.

The other characteristic change is areas of decreased density in the shaft, or the middle of the bones, and these show up in the X-rays as areas of decreased density. When we examine people who have had a sufficient amount of radium, we see these areas of either increased or decreased density which are scattered throughout the skeleton, and

these characteristic changes are one of the most reliable clinical methods we have at present for determining the early effects, or the first detectable effect, of radioactive materials in man.

Chairman DURHAM. What kind of a dose, Doctor, was that received by the bone structure in figure 2 of your statement?

Dr. LOONEY. This patient had 1.3 micrograms of radium, sir. This is about 13 times the present accepted MPC for radium.

In figure 4 you will note that this is a very detailed microscopic picture of radium being deposited in one of the fundamental units of the bone, known as the Haversian system. You will note the alpha tracks from the radium coming from those two Haversian systems, and this relates to the black area you saw on the autoradiograph of the whole bone. This is a microscopic picture showing the radium deposited in the small area. (See p. 1178.)

Representative HOLIFIELD. Do you have that same picture on the screen?

Dr. LOONEY. Yes, sir, I do. This is the picture here [indicating]. I might point out that here [indicating] is the area of the increased density that you see at the heads of the bone here and here [indicating]. The areas of decreased density are in here and here [indicating].

The areas that you will notice here [indicating] are the areas of destruction in the bone, and this is an X-ray of the bone showing the areas of increased density and the areas of decreased density, and these are changes characteristic of radium deposition. It is the best clinical method we have of determining the effects of radium.

Representative HOLIFIELD. Is it your judgment that the strontium 90 would have the same effect?

Dr. LOONEY. It is the best means we have of comparing the effects of strontium 90 to the effect of similar radio elements in man, and we have to go on the best available evidence we have.

Representative HOLIFIELD. Have you taken pictures of bones of mammals that have been subjected to strontium 90 exposure?

Dr. LOONEY. This has been done in some of the atomic energy laboratories. I have not been directly connected with this, and I am sure that some of the people in the audience could comment on that. Strontium and radium and calcium are deposited in the skeleton in similar manner; this is the basis of comparing the radium data with the present level for strontium.

This [indicating] is the picture of the alpha track, or the actual radiation from radium in one of the fundamental units of the bone, and this [indicating] is the underlying bone, showing an area of destruction, and another area showing no change.

Here [indicating] it shows the normal bone, and this is a typical osseous tissue adjacent to the normal bone, which results in these areas of increased density seen roentgenographically. In animals we see this atypical osseous tissue formed following plutonium, strontium, and radium administration, and in man similar changes are produced by radium. We consider that the mechanism is similar in the production of these changes.

Chairman DURHAM. What kind of rays are those, Doctor?

Dr. LOONEY. These are alpha rays. This is actually a picture taken by photographic emulsion over the bone itself. In other words, the track was coming up in the photographic emulsion, and it is like

taking a photograph, and this is the photograph of the alpha track.

Representative HOLIFIELD. No one has used "micrograms" before in the presentation. Will you relate that to a microcurie?

Dr. LOONEY. Yes. The microgram of radium and the microcurie are the same, because the microcurie was established from radium. So if I speak of micrograms or microcuries, as far as radium is concerned it would be the same.

Representative HOLIFIELD. That is what I wanted you to say for clarification of the record.

Dr. LOONEY. Yes.

Representative HOLIFIELD. Are the alpha or gamma rays which might be emitted of the same intensity and range in strontium 90 as in radium?

Dr. LOONEY. No, sir, they are not, because most of the radiation from radium is alpha radiation, and the radiation from strontium is from beta radiation.

Now you have heard the term "relative biological effectiveness" used. The RBE of radium has not been taken into consideration in the determination of the present MPC for strontium 90. Tho RBE [indicating] may be more than unity [indicating], so that this would permit the raising of the strontium level based on the radium data, if we were to determine that the effectiveness of irradiation from radium was greater than strontium in producing biological changes. In other words, it is generally considered that the alpha rays are more effective in producing biological changes per unit of energy dissipated to the material. These may be inherent safety factors that can be incorporated in present considerations of the MPC for strontium.

Representative HOLIFIELD. So if there would be a difference, it would be weighted toward the greater effectiveness of radium?

Dr. LOONEY. Yes, it would be weighted. Any change would be to the raising of the strontium MPC.

I would like briefly to comment about the hematological changes in these patients. The changes have been minor, and the only changes we have found have been minor changes in the size and shape of the red cells. In a few exceptions there have been anemias that have occurred in these people, but the hematological findings have been very minor changes compared to the skeletal changes.

I should like to go on to symptoms, and probably I should define what I mean by symptoms in these discussions. I shall refer to symptoms as the time when the patient becomes subjectively aware of these skeletal changes which we see. In other words, we first see skeletal changes in many of these people who have no symptoms at all. When skeletal changes progress to the point that the normal configuration of the bone is destroyed, symptoms usually occur the patient may have a fracture of the femur, or he may have destruction of the hip, and he limps, then these denote symptoms. The patient is aware these skeletal changes are present.

In going over these patients, there have been 11 patients of the 78 who have had destruction of the hip, the head of this [indicating] hip bone, so that they walked with a limb. All of these 11 patients have had seven-tenths micrograms or more of radium in their bodies.

There have been five patients with fractures of the femur. Some of these fractures have occurred from very minimal trauma. I remember one patient we examined had a fracture of the femur after

her husband came to a sudden stop at a stoplight, and the pressure of her foot on the floorboard of the car caused this fracture of the femur. So that the skeletal system does become more fragile, after a period of time, with these people in this range.

Representative HOLIFIELD. How did that particular patient receive that does of radium?

Dr. LOONEY. This patient was a luminous dial worker, sir, and she worked at Ottawa, Ill.

If you will turn to chart 1, you will note that this is the summary of the X-ray findings of 32 patients who had a complete skeletal survey. These patients were arranged in the order of increasing amounts of radium in the body. The frequency with which these characteristic skeletal changes, which I have shown to you, have occurred, were plotted as a function of the amount of radium in the body. You will note from the left hand vertical bar that there were 15 patients having between five-tenths and 1 microgram of radium in the body. You will notice that about 15 percent of the total bones that could be involved had these characteristic changes. (See p. 1174.)

There were 8 patients between 1.1 and 2 micrograms of radium, and you will notice that the frequency goes up to about 55 percent, and that between 2.1 and 14 micrograms of radium it goes up to about 60 percent.

If you will turn to table 1, you will notice that in the first group of patients, the average age was 49; the average age of the second group was 52; the average time of retention in the first group was 20 years; the average time of the second group was 22 years; the average age of the third group was 61 years; and the average time of retention was 22 years. (See p. 1174.)

We have a group of people who are about the same chronological age, who have radium retained for about 20 years, in which we can show a correlation between the frequency of these characteristic changes and the amount of radium in the body.

I think this is probably one of the most significant clinical observations that has been made—the correlation an objective clinical change with the amount of radium in the body within a specific dose range. I want to emphasize that extrapolation of the result of this clinical data either one way or the other would present many difficulties.

Chairman DURHAM. How did these patients receive this, Doctor?

Dr. LOONEY. With two exceptions, all of the people received this for medical purposes.

Chairman DURHAM. For treatment of other diseases?

Dr. LOONEY. Yes, sir; for the treatment of other diseases.

An important point to bring out here is the fact that people with 10 and 15 micrograms of radium did not have a proportionate increase in skeletal changes. In other words, we did not see people with greater amounts of radium in the body having greater changes. This would be consistent with the hypothesis that the changes that we see are the result of the dynamic interrelationship between the destructive processes and the reparative processes of the body. If we had radium with some other destructive skeletal disease, we might see changes at a much lower level than if the patient had no disease. Radium, plus condition A plus condition B might produce changes at 1 microgram. Radium, plus condition B might produce changes at 5 micrograms, and radium alone might produce changes at 10 micro-

grams. This is consistent with the hypothesis that the body is constantly repairing itself from destructive changes. When the body can no longer repair these changes, then permanent changes occur, in regard to radium, the skeletal destruction can be seen on roentgenographic examination.

Representative HOLIFIELD. As a term of common reference, would you say that any effect upon the bone is usually referred to as a tumor or cancer of the bone?

Dr. LOONEY. No, sir.

Representative HOLIFIELD. Or is there a differentiation between those two?

Dr. LOONEY. Yes, sir; there is quite a differentiation between those two.

Representative HOLIFIELD. Will you explain that for the record?

Dr. LOONEY. Yes, sir. These changes which we have seen—these changes here [indicating]—are minor changes, and are from abnormal bone formation. The areas here [indicating] are from small areas of destruction in the bone, and these can be seen in other conditions but usually not with the distribution and the characteristics seen in the radium patients. In other words, this is not diagnostic of radium, but it is very characteristic, and there are very few other medical conditions which will produce the same picture. I might say other nonmalignant medical conditions.

Chairman DURHAM. Doctor, did any of these patients in this group develop cancer from the normal treatment of other diseases from this radium?

Dr. LOONEY. I want to go into the number of tumors that have developed in these people, sir. I could not say whether these developed tumors from other conditions. All I could say is that a very large number of these people developed bone tumors, and out of proportion to other groups of people.

Of these 78 patients, 15 people have developed tumors.

If you will refer to figure 14, you will see the distribution of tumors that have occurred in these patients. You will notice that they usually occur at the end of the long bones, in the same areas in which you see these areas of abnormal bone formation.

I would like to read from that portion of the statement (p. 1170) entitled "Bone Tumors."

The 15 malignant tumors which developed in the 78 patients recently evaluated were found in individuals containing from 0.5 to 10 micrograms of radium in their bodies. The patient having 0.5 microgram of radium was a luminous-dial worker. It is reasonable to assume this patient ingested mesothorium and radiothorium. The patient with the lowest radium concentration, who had received radium medically, had 0.9 microgram of radium. The patient with the lowest concentration of radium, which was considered not to be contaminated with members of the thorium decay series, and who had developed a bone tumor, had 3.6 micrograms of retained radium.

It is important to emphasize that the luminous-dial workers used not only radium, but mesothorium and radiothorium. We have only measured radium, so we have not taken into consideration the radiation dose from either mesothorium or radiothorium.

The accumulated radiation dose with 3.6 micrograms of radium was estimated to be about 5,000 rads during the 25 years from radium administration until tumor formation.

Some of these people were selected because of symptoms. The number of bone tumors in the patients which were not discovered because of symptoms were located in a review of the records. We find that there is a frequency of about 2 percent in this unselected group as compared to a frequency of 14 percent of the entire group of 78 people. Although this is not conclusive, I do think it should be considered as it suggests this may be a biased group of people with whom we are dealing.

Because of the major interest in the possibility of bone tumor induction by radiation, I have taken two comprehensive articles in which the investigators have summarized the cases in which bone tumors have been produced following external radiation.

Vaughan in 1956 reported 39 cases of sarcoma arising in bone following external radiation have been recorded in the literature. The latent period between receiving radiation and the development of the tumor was 3 to 11 years. The radiation dose was not known in all of these cases; however, in most recorded cases it was estimated to be usually greater than 3,000 roentgens (1,500 to 7,000 roentgen range).

Cruz et al. in 1957 reported an additional series of 11 cases in which the bone tumors developed from 4 to 24 years after external radiation. The total radiation dose given ranged from about 1,000 roentgens to 5,000 roentgens, and was given over a period varying from 1 month to 9 years.

I should like to comment now on the possibility of bone-tumor production from strontuim 90, based on this information of tumor induction following external and internal radiation in man.

The assumption is often made that the incidence of the effect of strontium 90 is proportional to the magnitude of the dose. This assumption has been used to estimate the bone tumors which may be produced from the low concentrations of strontium 90 in the skeleton from fallout. There is no exact evidence either proving or disproving this assumption, but there is some clinical evidence which suggests that this assumption is overcautious.

The 50 bone tumors which have been known to have been produced in man from external radiation, and reported, were summarized in the previous section. The skeleton in the localized area of tumor induction received at least 1,000 roentgens, and usually more than 3,000 roentgens of radiation. If it is assumed that the radiation dose to bone is greater by a factor of 2 than the measured skin dose—in other words, the radiation going into the bone would absorb more radiation than the dose measured at the skin. So we are assuming it may be more than a factor of 2, maybe greater than this, but we are saying this as a reasonable estimate—then the minimum observed carcinogenic dose from external radiation would be about 2,000 rads, with the majority of the tumors being produced by more than 6,000 rads of external radiation.

Representative Cole. I would like to ask Dr. Looney, Mr. Chairman, to explain his statement that there is some clinical evidence which suggests that the assumption is overcautious, the assumption being that the incidence of the effect of strontium 90 is proportional to the dose. Now what do you mean when you say "there is some

clinical evidence which suggests that this assumption is overcautious." In what way?

Dr. LOONEY. I am saying that the minimal carcinogenic dose that we have reported for tumors to be produced in man is in the order of 2,000 rads. Based on the present clinical evidence we have today, we cannot prove or disprove that smaller doses would produce tumors, but I am just presenting to you the present evidence we have in man known to produce tumors. I am just saying that this assumption might be overcautious.

Representative COLE. What do you mean by "overcautious"? That is what I want.

Dr. LOONEY. May I come back to this at the end of these comments? Maybe this will clarify this statement.

What I have attempted to do is to present the order of magnitude of radiation we are dealing with. The following estimates on strontium 90 are based on the assumption that strontium 90 will be present in the body over a life span of 70 years. If we assume it is in equilibrium with bone or there is a constant intake of strontium 90, it would tend to approach a uniformity in bone.

Estimates which we can make from this information about the levels of strontium 90 necessary to produce bone tumors, skeletal roentgenographic changes, and total skeletal radiation from background radioactivity are as follows: Ten microcuries of strontium deposited in the skeleton for 70 years would give an estimated dose of about 2,000 rads. This is the minimum radiation dose recorded which has produced a bone tumor in man. This should give some idea of the magnitude of strontium levels which may produce bone tumors in man. You will notice that 6,000 rads is the estimated amount of radiation known to produce most tumors. The amount of strontium 90 which would deliver 6,000 rads to the skeleton over a life span of 70 years would be in the order of 30 microcuries.

The minimum radiation known to produce tumors in man is in the order of 2,000 rads, which would be 10 microcuries. The present MPC for industrial workers is 1 microcurie, and this would give 200 rads over a 70-year period. (The tenth of a microgram of radium would also give about 200 rads.) The total dose from natural radiation, based on the estimates of Dr. Robert Dudley of Massachusetts Institute of Technology, from all sources of radiation to the skeleton over a life span of 70 years, would be in the order of 10 rads. The sunshine unit, 1 times 10 to the minus 3 microcuries of strontium, would deliver about two-tenths of a rad to the skeleton in 70 years.

I will leave this up on the board so you can refer to it as the order of magnitude, and I will try to keep all of the units in rads so that this will give a basis for comparison.

I should like to go back to my statement in the section titled "Comments on * * * Bone Tumor Formations * * *." (See p. 1171.)

The patient with the smallest total body radium known to induce tumor formation, in which the possibility of contamination of the thorium series is unknown, died from a bone tumor in 1952. The estimated total body radium was 0.9 microgram. The time after administration is unknown, however, it is reasonable to assume that it was about 25 years. Based on the estimates above, the patient would have received a total accumulated does of about 1,800 rads during the 25-year period.

Histopathological changes have been demonstrated by roentgenographic examination of the skeletons of radium patients prior to development of the tumors. It is generally considered that the bone tumors developed in or around areas of atypical osseous tissue formation. Bone tumors have been shown to develop in or around the abnormal bone formation in animals given plutonium, strontium, and other radio elements.

If it could be shown that these histopathological changes are preliminary steps to bone tumor formation, then it could be assumed that as long as the body reparative processes prevented the abnormal bone formation, bone tumors would not develop. It should be emphasized that the associated histopathological changes seen prior to bone tumor formation in the radium patients may be coincidental findings. Proof of a correlation must await a better understanding of tumor induction by radiation.

Now there is one other bit of information in which I must emphasize little reliance can be placed. However, it is the best available evidence we have in man. This information pertains to the latent period of tumor development in relationship to the magnitude of the dose.

In reviewing the latent period for tumor induction in the luminous dial workers reported by Martland in 1931, it was found that the latent period for tumor formation was about 5 to 10 years in 6 patients who developed tumors. Only 3 of these patients had estimates of total body radium reported, and these estimated were 6, 15, and 50 micrograms.

The 8 luminous-dial workers who were examined in the recent Boston-Chicago investigations, and who died from bone tumors, lived for an average of 25 years after beginning employment. The average total body radium was 3.4 micrograms—range of 0.5 to 10 micrograms.

We have very meager data, but there does seem to be an inverse relationship between the latent period and the radiation dose necessary to produce bone tumors. The estimates based on this would be in the same order of magnitude as the estimates we have by the known radiation dose that produces bone tumors in man.

Therefore, the available clinical information we have at present indicates that the radiation dose for bone tumor production in man from both internal and external radiation is in the order of 2,000 rads.

The present MPC for radium, as I mentioned previously, was established in 1941. The fact that we are finding changes now at four-tenths of a microgram, which is four times greater than the MPC, is probably offset by the confidence in the larger group of patients which we have studied for longer periods of time. It is reassuring that it has not been necessary to change the MPC of radium over this long period of time, in view of the large amount of information that has been accumulated since it was established.

I have listed some of the factors which may permit the raising of the present levels for strontium 90. As I have pointed out, estimation of the mesothorium and radiothorium content in luminous-dial workers is being carried out. If it is found that the mesothorium and radiothorium contribute significantly to the dose, this would permit raising the present levels.

The characteristic changes we have seen may occur in the normal population, and further studies may permit us to obtain a better

understanding of how these changes are produced, thereby permitting a raising of the MPC.

As I mentioned in the introduction, most of these people were studied beginning about 15 or 20 years of age, so we have a gap in our knowledge of the younger age groups, which might necessitate lowering the present level. The present MPC is based on our present methods, and knowledge of the clinical changes produced by radioactive materials. It is possible that other subclinical effects may occur which may necessitate lowering the MPC.

In summary, it is considered that the best estimates which can be made in regard to the effects of strontium 90 over a life span of 70 years on the present incomplete information on the effects of radium in man are as follows:

The skeletal content of strontium 90 necessary to produce a bone tumor in a life span of 70 years would be in the order of 10 microcuries of strontium.

The skeletal content of strontium 90 necessary to produce significant changes, such as destruction of the hip would also be in the order of 10 microcuries of strontium over a life span.

The skeletal content of strontium necessary to produce minimal skeletal changes, which were demonstrated roentgenographically, would be in the order of 2 microcuries of strontium.

It should be emphasized again that these estimates of the concentrations of strontium 90 which may produce skeletal damage are the result of estimates based on the available information at present.

Representative HOLIFIELD. Have you finished, Dr. Looney?

Dr. LOONEY. Yes.

Representative HOLIFIELD. Are there any questions of Dr. Looney?

Representative VAN ZANDT. Mr. Chairman?

Representative HOLIFIELD. Mr. Van Zandt.

Representative VAN ZANDT. Dr. Looney, you have spelled out for us the effect of radium on the skeleton and explained how it produced bone cancer. Has radium in any way, shape, or form affected the blood to the point of developing leukemia or arthritis?

Dr. LOONEY. As I mentioned, the hematological changes in these people have been minor. In one case the patient died from renal insufficiency and there was a question of leukemia, but I would have to look this up.

Representative VAN ZANDT. What about arthritis?

Dr. LOONEY. Arthritis—I suppose the effects of radium might be considered a destructive form of arthritis. These people get destruction of the hip so this is, in a sense, a form of destructive or degenerative arthritis.

Representative VAN ZANDT. Dr. Looney, to your knowledge, has radium produced any other effects to the human body other than bone cancer?

Dr. LOONEY. That I know of, no sir. The major effects are the skeletal changes, and the bone tumors.

Representative HOLIFIELD. Dr. Looney, your presentation has been very valuable, and particularly the well-documented written presentation, which will be included in toto in the record.

I appreciate particularly having the pictures of the bone structures that are represented by your clinical and experimental experience in the record.

Thank you very much.

(The prepared statement together with "A Study of the Dynamics of Strontium and Calcium Metabolism and Radioelement Removal" submitted by Dr. Looney follows:)

THE BASIS FOR THE PRESENT MAXIMUM PERMISSIBLE CONCENTRATION FOR RADIUM AND ITS RELATION TO THE MAXIMUM PERMISSIBLE CONCENTRATION FOR STRONTIUM 90

A statement perpared for the Joint Congressional Committee on Atomic Energy on the subject "The Nature of Radioactive Fallout and Its Effects on Man," June 4, 1957, by William B. Looney, M. D.,[1] the John Collins Warren Laboratories of the Huntington Memorial Hospital of Harvard University, Massachusetts General Hospital, Boston, Mass.

INTRODUCTION

Man is constantly confronted with toxic agents in his environment, which, if present in sufficient quantities, may produce temporary or lasting changes. By the accumulation of clinical and experimental information about the quantity of these toxic agents which produce minimal changes, safety measures are established. The present maximum permissible concentrations for radioelements in use today are based primarily on the results of clinical and investigative studies made over the past half century.

The principal sources of material for the study of the effects of internally deposited radioactive materials in man have been individuals who were employed in the luminous dial industry and persons who received radium for medical purposes. Radium salts had been given orally and intravenously for hypertension, arthritis, anemia, and other medical disorders from about 1915 to 1930. The painting of watch dials with luminous materials containing radium, mesothorium and radiothorium started in this country in about 1914. Adequate safety measures were not taken until about 1925–27, following the deaths from bone tumors, anemia, and crippling bone lesions which occurred in some of these workers (41).

The first report in regard to the maximum permissible concentration (MPC) for radium was made by the National Bureau of Standards in 1941 (9). Seven individuals, having from 0.02 and 0.5 micrograms of radium in their bodies from 7 to 25 years had no noted changes referable to the deposition of radioactive materials. However, death had occurred in patients having as little as 1.2 micrograms of radium. The maximum permissible level of body burden for the amount of radium which remains after early rapid elimination was considered to be 0.1 micrograms.

Two investigations of 50 radium patients and 28 luminous-dial workers were made in Boston and Chicago and recently reported (3, 25). As a result of these two investigations, greater reliance can be placed in the MPC for radium. These investigations have given information about the effects of radium deposited for long periods of time in quantities at or near the present MPC. One of the most important results of the recent investigations is that a relationship between an objective clinical finding (skeletal roentgenographic abnormalities) and the physical estimate of total body radium could be made within a specific dose range.

This report is a condensation of a review article published recently in the Journal of Bone and Joint Surgery (27), which summarizes the results of studies made on the radium patients and the luminous dial workers over the past 40 years.

The clinical course following the deposition of varying amounts of radium has been divided arbitrarily into two categories in this report.

A. Patients with total body radium content at or near the MPC of 0.1 micrograms with either no detectable clinical effects or minor skeletal changes

Thirteen of the seventy-eight patients studied in the Boston-Chicago investigations had between 0.01 and 0.4 micrograms of radium, and with the exception of 2 cases listed below, none had either symptoms or skeletal changes which

[1] Clinical and research fellow in medicine, Harvard Medical School; visiting fellow in physics, Massachusetts Institute of Technology; special U. S. Public Health Service fellow of the National Cancer Institute.

could be attributed to radium. One patient with 0.4 micrograms of radium, age 83 years, was incapacitated with arthritis, therefore it was difficult to differentiate between the skeletal changes which may have been produced by radium from those which may have been produced by the skeletal disorder and disuse atrophy. Roentgenographs of the teeth of the other patient demonstrated areas of resorption in the teeth similar to those seen in other patients with greater amounts of radium. This patient was 32 at the time of examination. He had received radium water as a tonic between the ages of 8 to 10 years. The total body radium was only 0.15 micrograms of radium. It was considered that the early age of administration of radium may account for the dental changes with only a 50 percent larger radium content than the MPC of 0.1 micrograms.

B. Chronic effects of radium

1. Patients studied during the first and second decades following the initial medical and industrial use of radium (1915–35).—These patients were symptom free for about 10 years (31). Following the latent period, various changes relating to the skeleton began to develop. Death usually occurred from tumors of the skeleton, anemias or crippling bone lesions, or all three. Twenty-five of these cases were reported in the two decades which followed. Estimates of the radium content of the body began to be reported on these patients; however, the reliability of these estimates is hard to ascertain. These estimates ranged from about 5 to 100 micrograms of radium.

2. Patients studied during the third and fourth decades following the initial medical and industrial use of radium (1935–55).—Sixty-five of the seventy-eight patients evaluated in the recent Boston-Chicago investigations, having between 0.5 and 23 micrograms of retained radium, had either roentgenographic changes or symptoms, or both, which could reasonably be attributed to radium. The exceptions to this were three patients having betwen 0.5 and 1 microgram of radium having no skeletal abnormalities demonstrated roentgenographically. There was no proportionate increase in either the frequency or severity of the roentgenographic changes and symptoms with increasing amounts of radium in the body. The wide variation in the clinical abnormalities is consistent with the hypothesis that the changes observed are the result of a dynamic relationship between the reparative processes of the body and the destructive processes of the body acting in conjunction with the releterious effects of radium.

The mean age of the 28 luminous dial workers in the Boston-Chicago study was 21 years at the time of employment, and the mean age of the 50 patients at the time of radium administration was 34 years. The average time of retention was about 25 years in both groups, with a range of about 10 to 35 years. The average age of the patients in 1951 was about 50 years (range from 40 to 80 years). Seven of the 50 patients given radium have died; 5 died from tumors, 1 from anemia, and 1 from multiple causes; 11 of the 28 luminous dial workers are dead; 8 died from tumors, 1 from broncho-pneumonia, 1 from a urinary disorder, and another from renal insufficiency and leukemia. The average age at death for the radium patients was about 65 years, and the average age at death for the luminous dial workers was about 45 years. The average time of deposition of radium until death of the 18 patients was about 25 years, and average total body radium was about 5 micrograms.

As far as we have been able to determine, 10 of the 50 radium patients and 16 of the 28 luminous dial workers were discovered because of symptoms. It is apparent that these patients represent a biased sample from the population of radium patients and luminous dial workers. Correction for this biased sampling should be made in any attempt to relate the frequency of bone tumors and bone destruction in these patients with estimates of the frequency of these changes with comparable amounts of strontium 90.

RADIUM ELIMINATION

Radium is considered to be dispersed throughout the soft tissues and the skeleton when it first has been taken into the body (43). Most of the radium is eliminated during the first week (42, 43) (fig. 1). Fecal excretion is the major route of elimination in early and late cases. From 90 to 97 percent of the radium which is eliminated is eliminated in the feces and only 3 to 10 percent is eliminated in the urine (2, 35, 42). It has been reported that the rate of elimination following inhalation or ingestion is more rapid than that following intravenous administration (40, 42). Results from recent studies, however, indicate that these differences in the rate of elimination are not so pronounced as it was previously thought (26, 30, 35). Within a matter of

months, 90 to 99.9 percent of the radium is eliminated (40, 43). The age, the total amount of radium injected, and the estimates of the injected dose in 19 patients at 6 months, 12 months, and 20 years, have been reported (35). The average amount of the injected radium remaining at the times these estimates were made was 4.7 percent, 2.2 percent, and 0.8 percent, respectively.

The amount of the remaining radium eliminated daily becomes less and less (26). The available clinical data on the coefficient of elimination[2] of radium are given in figure 1. The marked change in the coefficient is elimination at 1 week has been considered to be the result of the elimination of the principal portion of radium from the soft tissues and the gastrointestinal tract and the change at 1 year has been considered to be the result of the elimination of the principal portion of radium from the more accessible parts of the skeleton. It is reasonable to conclude that the decreasing rate of elimination of radium is from the more inaccessible parts of the skeleton after 1 year.

About 15 to 35 percent of the absorbed radium is eliminated the first day. The amount of the remaining radium eliminated daily after 1 week is less than 1 percent. After about 10 years, it varies from 0.002 to 0.009 percent of the body content. The coefficient of elimination after about 20 years varies from about 0.002 to 0.016 percent of the body content (35, 43).

THE MANNER OF RADIUM DEPOSITION IN THE BODY

A. Autoradiographic study of radium deposition

Entire bones were sectioned serially and a comprehensive picture of distribution throughout the entire bone was obtained by placing the sections on roentgenographic film (3, 23). The precise manner of the deposition of radium was obtained by detailed autoradiography (1, 3, 23). Histological sections were covered with a photographic emulsion. After the emulsion and staining had been developed, simultaneous study of radium deposition and histopathological change was made.

Radium was found in small areas of high focal concentration irregularly distributed in both compact and cancellous bone. In compact bone only a small percentage of the Haversian systems and interstitial lamellae had appreciable concentrations of radium. In some instances radium was concentrated in 1 or 2 concentric lamellae, in other instances it was deposited around the central canal or periphery of the Haversian system.

The areas of radium concentration in travecular bone were usually 5 to 15 micra in the greatest dimension. However, there was a wide range in size and shape of these areas, and they were found at any depth within the trabecula. In some instances linear concentrations ran parallel to the curvature of the trabecula for 50 to 100 micra. Heavy and rather uniform concentrations of radium were present at the junction of the articular cartilage and the traveculae of the long bones in the gross autoradiographs. In the study by gross autoradiography it was found that frequent small highly concentrated areas resulted in outlining the bone contours (fig. 8). Some cementing lines were clearly outlined by heavy concentrations of radium.

In some sections exposed for long periods of time there was a much less concentrated and a much more uniform distribution of radium. These findings are in agreement with existing theories that radium has more than one principal mode of deposition. The small highly concentrated areas may have been areas in which bone formation was taking place at the time of administration or redistribution. The more uniform and less dense distribution may be the result of inorganicion exchange (23). (See figs. 2, 3, 4, 5.)

HISTOPATHOLOGY

The histopathological changes which are most important diagnostically are: (1) the formation of an atypical osseous tissue in the trabecular spaces of cancellous bone, and (2) well differentiated areas of destruction in compact bone.

Martland divided the changes in the skeleton into three stages, all of which are primarily concerned with the bone marrow (31). In stage III, however, he did state that bone absorption and considerable decalcification did occur along with the replacement of bone marrow and noncellular fibroblastic tissue.

[2] The coefficient of elimination is equal to the amount of radium eliminated per unit time (days) divided by the amount of radium in the body at the time the elimination measurements were made.

Studies of the skeletal changes produced in animals following the deposition of radioactive elements clarify the mechanism of production of the histopathological changes that have been found in human material. Heller and Bloom and Bloom concluded from their studies of such bone-seeking radioactive elements as strontium, yttrium, plutonium, and radium that similar changes were produced by all of these radioactive elements.

Following radium injections in mice the most spectacular change was a dense atypical bone in the metaphysis. This started from the proliferation of spindle cells which formed a dense fibrous tissue. Areas of calcification occurred in this fibrous tissue to form an atypical osseous tissue. It was also found to lesser degree in the shafts of the long bones and in the vertebrae. This was accompanied by the disappearance of osteoblasts, swelling and degeneration of cartilage cells, and death of most of the osteocytes. Repair began along with the destricutive effects of radium. In the lower dose ranges, reversible changes occurred so that in a matter of months normal bone was found on histological examination. Larger amounts of radium producted more severe and lasting changes. The epiphyseal cartilage varied tremendously in width, and the entire metaphysis was abnormal in appearance. The atypical osseous tissue remained in these animals at all intervals up to the termination of the experiment at 5 months.

The femoral shaft contained varying degrees of empty lacunae and dead oseocytes. The bones of the shaft varied from the relatively smooth contour to greater or lesser irregularities on the endosteal surface with projection into the marrow cavity.

Historical specimens have been obtained from 3 luminous-dial workers and 6 patients who had received radium. The radioactive elements had been present in the skelton from 12 to 35 years preceding biopsy and autopsy. Two luminous-dial workers and two patients who had received radium had bone tumors.

The histopathological changes were similar in certain respects to those changes found by Martland, Heller, and Bloom and Bloom (4). Atypical osseous tissue was present in cancellous bone. It was usually found near the articular surface of such bones as the humerus and femur, in addition to being found in the metaphyseal area. The atypical osseous tissue was laid down adjacent to the trabeculae in some areas. In some areas there was hyperplasia of the trabeculae, while in others destruction of the trabeculae was present. The trabecular spaces were usually filled with an acellular fibrous tissue. In general there was an absence of radioactivity in the atypical osseous tissue and accellular fibrous tissue was found in the autoradiographic study. In most cases, there was a prominent absence of osteocytes in the lacunae, and there was little evidence of bone regeneration.

In compact bone, the central canals showed a wide variation in size from normal to the nearly complete destruction of the entire Haversian system. A large number of the central canals were occluded with a dark staining material similar to the atypical osseous tissue in the trabecular spaces. There was usually an absence of cells in the lacunae. Minimal evidence of bone regeneration was observed, and areas of destruction usually were replaced with fibrous connective tissue.

In addition to the microscopic areas of destruction, macroscopic areas of destruction have been observed in compact bone 1 to 2 millimeters in width and 5 to 20 millimeters in length. Radium concentrations were rarely found in or around the macroscopic areas of destruction. Areas of transition in which both radium concentrations and microscopic change appear together have been found rather infrequently.

It has been shown that a correlation exists between the frequency of destructive changes and the amount of radium deposited in the body. It has been postulated that these macroscopic areas of destruction occur as the result of the fusion of adjacent central canals of Haversian systems undergoing destructive changes. It has been further postulated that the radium had been removed from the macroscopic areas of destruction by the time the changes occurred. If direct irradiation was the primary mode of production of the skeletal changes, more areas of transition should have been found in which both radium deposition and skeletal histopathological changes were present. It is evident that considerable difficulties are inherent in any attempt to reconstruct a pathological process which has been going on for 20 to 30 years from specimens taken at the termination of the process.

As a result of these observations, it is considered that radium deposited in the skeleton usually initiates a sequence of events which eventually produces patholog-

ical changes. These changes are probably the end result of many intermediate factors such as trauma, damage to blood supply, hormonal imbalance, decreased bone repair, and increased bone destruction from other causes. Evidence from the histological sections indicates that Haversian systems may undergo periods of resorption followed by periods of bone formation. There was a subnormal appearance of the bone in many instances. Some of the destructive changes may be the result of the inability of bone to maintain normal repair. It is evident that the relationship between radium deposition and skeletal change is complex. It is reasonable to conclude that when the destructive effects of radium and other deleterious intermediate factors become greater than the reparative processes of the skeleton, permanent alternations occurs (see figs. 6, 7, 8, 11, and 12).

HEMATOLOGICAL FINDINGS

In 1924, Castle, Drinker, and Drinker (8) reported the hematological findings of 22 luminous-dial workers. The erythrocyte count was below 4 million in 6 percent of these cases and above 6 million in 19 percent. The white-blood-cell count was below 7,000 in 27 percent of the workers. Abnormal erythrocytes occurred in 36 percent of the series. There was an increase in lymphocytes and monocytes and decrease in the polymorphonuclear neutrophils found on differential examination.

In 1943, the Public Health Service (41) made a study of 196 employees of luminous-dial-painting plants. Anisocytosis was found in 11 percent of these people, and poikilocytosis in 8 percent. The average erythrocyte count in the Public Health Service series was 4,300,000 as compared with an average of 4,500,000 in a series of 31 control patients.

Hematological data were available on four patients who died. Two of these patients died from malignant tumors—patient (R–24) and patient (B–7). Patient (R–44) died from aplastic anemia and patient (L–27) died from secondary infection and debilitation.

The marked pancytopenia that occurred in Martland's cases had not occurred in the patient evaluated in 1951. A short time before death, there were usually about 3 million erythrocytes per cubic millimeter and 10 grams of hemoglobin per 100 cubic centimeters. No hemorrhagic manifestations occurred in these patients. Some of Martland's cases had less than 1 million erythrocytes and less than 1,000 leukocytes per cubic millimeter shortly before death. He considered the anaemia which developed in his patients to be of a regenerative type resembling pernicious anemia, and he described the hematological changes in the following way: "The blood in this case showed a profound anemia, characterized by a large cell anisocytosis, by the presence of megaloblasts and by a marked leukopenia. There was not, however, a hyperbilirubinemia, and the van den Bergh tests were negative. The anemia is, therefore, not a hemolytic anemia. It is not an aplastic anemia, since there is marked embryonal blood formation. The fault lies in a long continued irritation of the hematopoietic system, the hemolytic or reticuloendothelial system being unaffected. There is a stage of stimulation followed later by sudden exhaustion of the erythroblastic and leukoblastic centers with the production of a rapid, fatal anemia with leukopenia, which fails to be influenced by any form of treatment." Red regenerative marrow was present in the femora of some of these patients.

These changes in the hematopoietic system are similar to those seen in the acute radiation syndrome. Most patients who lived less than 6 weeks following external radiation had hypoplastic marrow. Some patients who died at 4 to 5 months after exposure had diffuse myeloid hyperplasia which involved even such long bones as the femur. Occasionally the marrow appeared pink and gelatinous.

The bone marrow of patient (R–24) was studied in 1948, 18 years after radium administration. It was reported to be distinctly overactive. There was moderate erythroblastic activity with an excessive number of cells in mitosis without a shift to the left. The remainder of the cells were normal. The erythrocyte count was 5,300,000 per cubic millimeter and hemoglobin was 12 grams per 100 cubic centimeters at this time. The erythrocyte count was 3 million per cubic millimeter and hemoglobin was 9 grams per 100 cubic centimeters shortly before death in 1951. Small pink areas of hyperplasia was found in the femur and tibia at autopsy. Sternal marrow from patient (R–43) revealed extremely atrophic marrow shortly before her death in 1947. There were only small areas or erythropoiesis and the remainder of the marrow was composed principally of fat cells. No evidence of excess destruction, serious fat atrophy, or fibrosis

was observed. The hemoglobin at this time was 12.6 grams per 100 cubic centimeters and the erythrocyte count was 3,890,000 per cubic millimeter.

Patients who have over one microgram of retained radium are more likely to have anisocytosis, poikilocytosis, and hypochromia of the erythrocytes than those having under one microgram. However, significant hematological changes usually do not occur until late in the course of the disease.

In view of this additional information, it appears that little qualitative difference exists in the hematological response to internal or external radiation. If an individual had received large enough amounts of radioactive substances internally, hematological changes occurred which were similar to the hematological changes following exposure to large amounts of external radiation. In individuals who had received smaller amounts of either internal or external radiation, the hematological response at any given time was varied. The type and number of cells in the circulation at any specific time is the result of the natural survival of the cells and the balance between their radiosensitivity and their ability to recover from injury.

The red regenerative marrow that Martland described was in all probability an abnormal attempt of the hematopoietic system at increased production as a result of damage. Martland's term leukopenia anemia of regenerative type which was used to describe the hematological changes in the luminous-dial workers does not seem to be appropriate. The anemia that develops in these patients and the patients who had received radium would be more suitably placed in the category of primary refractory anemia in which either a hyperplastic or hypoplastic (aplastic anemia) bone marrow may be found. No leukemias have been found.

ROENTGENOGRAPHIC CHANGE

Areas of increased density have been found in cancellous bone on a skeletal roentgenographic examination. This roentgenographic change is the result of a typical osseous tissue in the trabecular spaces; infrequently it is the result of hyperplasia of trabeculae. Well-defined areas of decreased density were found in compact bone. These were the result of the destructive changes in the cortex of the bone.

These changes were divided into three groups, principally on a descriptive basis (24):

Group I: Areas of decreased density which were usually 1 to 2 millimeters in width and 5 to 20 millimeters in length in the long bones which gave a streaked appearance, and "punched-out" areas varying from 2 to 20 millimeters in the greatest dimensions present in the skull.

Group II: Areas of increased density usually associated with areas of decreased density with varying degrees of change in the trabecular pattern. These usually occurred in the femoral head, the humeral head, and the glenoid process, giving a mottled or motheaten appearance. There was an increase in frequency of biconcavities and collapse of the vertebras in patients having larger amounts of retained radium. Areas of increased density were found along the superior and inferior borders as well as small areas of increased density in the vertebral bodies.

Group III: The term "aseptic necrosis" has been used in referring to the changes in normal configuration. The heads of the femora, the bones of the feet, and the mandible were most commonly involved.

Serial roentgenograms of a few of these patients over long periods of time have been obtained. In most of the available serial roentgenographic studies, changes were not found until years after the deposition of the radioactive element. Periods of skeletal change may occur and may become stabilized or may improve. Later skeletal changes occur with increasing frequency.

For example, one patient (R–50) was given radium in 1922 (age 42 or 44). Ten years later skeletal roentgenographic changes characteristic of radium deposition occurred primarily in the mandible. These changes gradually improved. In 1940 (age 60) a significant increase in skeletal involvement occurred. There was a gradual increase in frequency and severity until her death in 1949. Roentgenograms of the skull of another patient (R–24) in 1948 demonstrated 12 areas of decreased density; the number of areas had increased to 22; however, there was minimal increase in the size of the areas. The size of these areas usually did not become greater than dimensions given in the description of the roentgenographic findings. Infrequently, however, they may be as great as 3 to 4 centimeters in diameter. The usual sequence of events was an increase in numbers, as well as an increase in the number of bones involved.

It is evident from these and other serial roentgenograms that these changes do not bcome detectable until many years after the deposition of radioactive elements. The possibility of skeletal histopathological changes being produced and remaining undetected reontgenographically for years must also be considered. There were no roentgenographic changes found on complete skeletal roentgenographic examination of patient (R–13) in 1950, with the exception of an aseptic necrosis of the right femoral head. However, minor histopathological changes characteristic of the deposition of radioactive elements were found in sections of the left fibula of this patient. In 1954, roentgenographic changes characteristic of the deposition of radioactive elements were present in the fibula and other long bones.

It has been shown that skeletal histopathological changes are reversible in animals following the deposition of radioactive elements. The history of another patient (R–50) demonstrates that skeletal changes as seen by roentgenogram are reversible in man following the deposition of radioactive elements. It is reasonable to assume, therefore, that reversible skeletal histopathological changes occur in man, as well as in animals, following the deposition of radioactive elements. When the reparative processes are able to be maintained at a level equal to the destructive processes, no detectable changes occur as seen by roentgenogram. If the ability to maintain skeletal repair is impaired or decreased, more and more permanent alterations probably result from the imbalance between the reparative and destructive processes.

Histopathological changes have been present to such a degree that roentgenographic changes have been found in many patients who are symptom-free. However, significant clinical changes usually do not occur in the absence of skeletal roentgenographic change. The results of skeletal roentgenographic, autoradiographic, and histopathological studies made on serial bone sections indicate that repeated skeletal roentgenographic examinations are the most satisfactory clinical methods for the early detection of skeletal alterations following the deposition of radioactive elements.

Thirty of the patients who were given radium for medical reasons and two luminous-dial workers were selected because each of these patients had had a complete skeletal roentgenographic examination. They were arranged in order of increasing amounts of retained radium from 0.5 to 14 micrograms, and the skeletal changes characteristic of the deposition of radioactive elements were tabulated. These patients were arbitrarily divided into three groups, those patients having between 0.5 and 1 microgram of retained radium, those having between 1.1 and 2 micrograms, and those having between 2.1 and 14 micrograms. Table I gives the age and sex of 32 patients 21 years after the deposition of radioactive materials.

Forty individuals were selected at random while undergoing physical examination at the Argonne National Laboratory for skeletal roentgenographic examination to act as a control group. It would have been desirable to have matched controls; however, the results of these roentgenographic examinations greatly minimized the possibility of the minor changes being present to any significant degree in the general population.

Five luminous-dial workers having between 0.02 and 0.4 micrograms of radium and 4 radium patients having between 0.01 and 0.4 of radium had complete skeletal surveys. One 83-year-old patient (0.4 micrograms of radium) had roentgenographic changes characteristic of radium deposition. The interpretation of these changes was difficult because of the marked arthritic abnormalities. Another patient with 0.15 micrograms of radium had areas of resorption of the teeth.

The five bones (skull, radius, ulna, tibia, and fibula) which were most frequently the sites of decreased density were first tabulated (chart I). The frequency of involvement was expressed as a percentage of the total number of bones that could possibly be involved. No distinction was made between unilateral or bilateral involvement, since the long bones were involved bilaterally in all but about 10 to 20 percent of the cases.

For example, in the 15 patients having between 0.5 and 1 microgram of radium, a total number of 75 bones could be involved; only 6 bones had changes characteristic of radium deposition or about 10 percent of the total number of bones. In group II, about 55 percent of the bones had characteristic changes, and in group III about 65 percent of the bones were involved.

Attempts were made to find some correlation between the severity of bone changes and increasing amounts of radium. The skeletal changes were divided into six grades of severity (27). With increasing amounts of retained radium

in the body, a proportional increase in roentgenographic changes does not occur. In addition, there is a marked individual variation in the amount of retained radium in the body. In some patients who had the greatest amounts of retained radium, only minor changes occurred, while other patients who had only one-fifteenth to one-thirtieth as much had more severe skeletal changes. Chart II graphically demonstrates this clinical observation in regard to the roentgenographic changes. Patients in group III had about 5 times as much radium as those in group II; however, there is only a 10 percent increase in the frequency of involvement. This lack of correlation between group II and group III is further emphasized by the fact that the average age of group III is 60 compared with an average age of 50 in group II. This finding and the finding of a significant increase in roentgenographic changes and symptoms at 1 microgram, even though the luminous-dial workers were 13 years younger, are suggestive that age at the time of deposition is not a major factor in the eventual production of roentgenographic changes. The fact that some of the patients had between 0.1 and 0.5 microgram of radium deposited for 25 to 30 years and had no roentgenographic changes is suggestive that time of retention per se may not be a major factor in the eventual production of roentgenographic changes. It is to be emphasized that these observations, suggesting that the time of deposition and the length of retention are not important, may well be the result of biased sampling of the patients, as well as an inadequate number of patients.

The most important result of these studies is that a definite correlation has been made between an objective clinical finding and the estimated amount of radioactive element retained in the body. For the first time, a semiquantitative relationship between the frequency of the roentgenographic changes and retained radium has been established within a certain dose range. No characteristic roentgenographic changes have been observed in patients having under 0.1 microgram of radium and relatively few changes have been found in patients having between 0.1 to 0.5 microgram of radium. Between 0.5 and 1 microgram of radium changes began to occur with increasing frequency and those patients having over 1 microgram of radium had a considerable increase in the frequency of the roentgenographic changes when compared with the patients having under 1 microgram of radium. (See figs. 9, 10, 11, 13.)

SYMPTOMS

Symptoms which can be reasonably attributed to radioactive element deposition usually result from destructive changes in the skeleton in patients with small amounts of radium. When symptoms do occur as a result of skeletal change, there are usually not severe in comparison with the extent of skeletal damage. In some instances, there is neither a progression of the skeletal lesions nor of the symptoms following the production of the skeletal change. For example, aseptic necrosis of the head of the femur in one patient developed in 1940 (age 30 years). This was followed by limping and discomfort on walking. However, during the period between the onset of symptoms and the examination in 1951, little progression of either limping or discomfort on walking occurred. There was also minimal discomfort following the aseptic necrosis of the head of the radius in another patient (R–23) since the beginning of symptoms in 1947. Another patient had aseptic necrosis of the head of the femur 22 years after the administration of radium at the age of 50 years (25, 27). She had no other symptoms or changes that could be related to the deposition of radioactive elements.

Skeletal changes usually occur in bones subject to weight-bearing or to repeated trauma (31). Aseptic necrosis usually occurs in the heads of the femora and the bones of the feet. Collapse of the veterbrae is occasionally found, while fractures almost always occur in the femoral shaft. One patient (L–27) fractured her left femur while pressing her foot to the floor of an automobile. Patients (L–14) and (R–35) sustained fractures of the shafts of the femur on minimal trauma. Healing of the fractures was delayed, but proper union occurred in all patients. Rarely, patients may have femoral fractures with permanent nonunion. Patient J. J. had collapse of some of the vertebral bodies with associated pain that required the wearing of a Taylor brace for control, while patient (R–44) had more marked vertebral changes with minimal discomfort.

Many of the patients did not have any symptoms which might be attributed to radium intake. Other than an increased risk of skeletal injury or tumor

formation, they may never have any recognized clinical changes as a result of radioactive element deposition.

In attempts to correlate clinical change with the amount of radium in the body, marked variations were found. The history of patient (R-49) illustrates this clinical observation. The only difficulty that he had was a march fracture of the foot which had healed uneventfully. The patient was asymptomatic at the time of examination in 1951 and only minor skeletal roentgenographic changes were present which could reasonably be attributed to the deposition of radioactive elements. Fourteen micrograms were present in his body, 15 to 30 times the amount present in some patients who had severe skeletal changes or tumor formation.

The time between the deposition of the radioactive elements and the onset of the first symptoms was analyzed in order to see whether any correlation could be made between this period and increasing amounts of retained radium. Twenty-one of the 25 luminous-dial workers had symptoms referable to radioactive-element deposition and 25 of the 50 patients who had received radium had symptoms that could reasonably be attributed to radioactive-element deposition.

The luminous-dial workers and patients who had received radium were divided into two groups. The first 10 patients of the luminous-dial workers who had symptoms and had between 0.1 to 1.5 micrograms of retained radium were compared with the 11 luminous-dial workers having between 1.6 and 18 micrograms of retained radium. The average time before symptoms occurred in the first group was 16 years and in the second group was 15 years. The 25 patients who had received radium who had symptoms referable to the deposition of radioactive elements were divided into 2 groups. The first 12 patients had between 0.7 and 4.2 micrograms of retained radium, the other 13 patients had between 5 and 22 micrograms. The average time before symptoms occurred in the first group was 17 years and in the second group was 16 years. There was no increase in the time interval before symptoms occurred in the first group, even though there was from about 10 to 100 times less radium in the body. It should be noted that the period of latency before the onset of symptoms that could reasonably be attributed to the deposition of radioactive elements varied from 1 to 32 years.

Since no relation between increasing amounts of radium and the time before symptoms occurred from deposition of radioactive elements was found, the frequency of involvement of the femur was examined to see if some correlation could be made with the retained radium. Nine patients who had received radium had aseptic necrosis of the head of one or both femora as did luminous-dial workers.

It is well known that aseptic necrosis of the femoral head usually occurs as a result of trauma or following fractures of the neck of the femur. It is also true that aseptic necrosis does occur in which the etiology cannot definitely be established. In these cases, it is considered that circulatory disturbances are the primary cause of the necrosis. The cause of the disturbance is poorly understood; it may be from gradual occlusion or from trauma (37). Unfortunately there is little information concerning the incidence of unexplained aseptic necrosis of the femoral head. Estimates of the occurrence of aseptic necrosis of the femoral head from all causes approximated 1 in 200 in an orthopedic practice.

The 14 percent incidence of aseptic necrosis of the femoral head in these patients seems unusually high in the absence of a history of antecedents trauma or fracture. It is interesting to note that all of the lesions occurred in patients having 0.7 microgram or more of radium in their bodies. The average time from the deposition of the radioactive elements until symptoms referable to the femoral head occurred was 15 years, approximately the same as that for symptoms in all other parts of the skeleton. The time of onset varied from 9 to 22 years.

Almost all of the fractures occurred in the shaft of the femur. Some of the patients fractured both femora, as well as sustaining refracture one or more times. Fractures following such minimal trauma as pressure of the foot on the floor of the car emphasize the fragility of the skeleton that may result from the deposition of radioactive elements.

Fractures of the femur occurred in 4 of the luminous-dial workers and in only 1 patient who had received radium. Again it should be noted that all of the fractures occurred in patients having 0.9 microgram or more of retained radium.

TUMOR FORMATION

The clinical course of patients in whom malignant tumors eventually develop is illustrated in the following case histories.

Patient (L–21) began to have symptoms as a result of skeletal changes 11 years after employment as a luminous-dial worker in 1934 (27). Several skeletal lesions occurred over a period of years following the deposition of the radioactive element. A biopsy specimen was taken from the left femur in 1950, following the clinical diagnosis of chronic osteomyelitis. The histological diagnosis at that time was a low-grade inactive fibrous osteomyelitis associated with recent slow-growing cancerous type of fibrous osteoma. In 1952 pain began to occur and to increase in frequency in the left femur, and the roentgenograms were interpreted as being suggestive of malignant changes in the medial condyle. The extremity was amputated and an osteogenic sarcoma was found throughout the femur on histological examination. The patient died a few months later.

Patient (R–24) had noted the onset of pain in the left foot 18 years (1948) after the administration of radium water (27). Roentgenograms of the foot a few months later revealed an area of decreased density in the left tarsal navicular. The condition became so severe that it necessitated the use of a cane. Roentgenograms at that time revealed marked destructive changes of the tarsal bones. Because of the marked increase in symptoms and the destructive changes in the foot in 1950, a biopsy was done and fibrosarcoma was diagnosed on histological examination of the specimen. The pain became generalized and required more and more analgesics to control; it was described as boring and burning in character. Intermittently, sharp knifelike pains occurred which lasted for a few seconds. The pain was not significantly influenced by motion, position, and temperature. The leg was amputated below the knee in February 1951. Examination of the amputated tibia revealed extension of the tumor. A sarcomatous lesion developed on the end of the stump a few weeks after the operation. The patient died in August 1951, as a result of generalized metastases. Areas of fibrosarcoma were found throughout the skeleton. In some parts of cancerous bone, it was difficult to distinguish between the fibrosarcoma and the fibrous connective tissue found in the trabecular spaces of patients without malignant involvement.

It is evident from the case histories of patients (L–21) and (R–18) that the transition from a benign to a malignant lesion may be similar to that in many skeletal diseases. Both of these patients were first considered to have osteomyelitis and then osteoid osteoma. In patient (R–17) the diagnosis of osteoid osteoma of the finger had been made 1 year prior to the diagnosis of osteogenic sarcoma. Characteristic histopathological changes due to the disposition of radioactive elements were found in reviewing the specimens from which these diagnoses were made.

The history of patient (L–8) emphasizes the need to follow these patients carefully. Patient has led a relatively normal life since 1934 as a result of prompt attention to symptoms occurring in the elbow. Following a biopsy and histological diagnosis of osteogenic sarcoma, the arm was disarticulated at the shoulder.

Figure 14 shows the sites of origin of the tumors that developed in 13 of the 78 patients. Eight of these patients were luminous-dial workers and five were given radium for medical purposes. Table II gives the age at the time of administration, the time from administration until the first symptoms occurred which could reasonably be attributed to the deposition of radioactive elements, the time from the first symptom until death, and the amount of retained radium. Since both groups of patients have approximately the same amount of radium retained in the body for about the same length of time it is not possible to make any differentiation between luminous-dial workers and patients who were given radium in relation to the estimated radium present. The average age at the time of employment in the luminous-dial workers was 17 years as contrasted with 39 years as the average age at the time of the administration of radium.

Most of the patients in whom malignant tumors eventually develop follow a similar course. There is a latent period followed by symptoms which usually developed from changes in weight-bearing bones and bones which are subject to repeated trauma. Later tumor formation occurs at a site which is usually not the site of the initial symptoms. When the malignant tumor develops, there may be a marked acceleration of the disease process and death usually occurs about 1 to 4 years after the symptoms began at the site where the tumor originated.

THE RELATION OF THE CLINICAL CHANGES TO THE AMOUNT OF RADIUM PRESENT IN THE SKELETON

A. Hematological changes

Minor changes occurred with greater frequency in the erythrocytes in patients having more than 1 microgram of radium than those patients having less than 1 microgram. The marked anemias found in the earlier cases were not present in the 78 cases studied recently. Two patients developed anemias a short time before death. Only one leukemia has been reported.

B. Roentgenographic changes

One of the most important results of the recent Boston-Chicago investigations was the ability to correlate the frequency of occurrence of roentgenographic changes characteristic of radium deposition with the physical estimates of total body radium. Thirty-two patients[3] having complete skeletal roentgenographic examinations were arranged in order of increasing amounts of radium and the changes tabulated (review section on roentgenographic changes.)

C. Symptoms

Symptoms[4] which can reasonably be attributed to radium occur as a result of changes in the skeleton. Symptoms which could reasonably be attributed to radium did not occur in any of the 78 patients who had under 0.4 microgram of radium. Nine patients who received radium medically and two luminous-dial workers developed destruction of the femoral head. The average time for symptoms to occur was 15 years (range 9–22 years). All of the patients who had aseptic necrosis of the femoral head had 0.7 or more micrograms of radium in the body. The 5 patients who had fractures of the shaft of the femur had 0.9 microgram or more of radium in the body.

The results of these investigations indicate that the relation between the destructive effects of the radioactive elements remaining in the body for long periods of time and the clinical changes produced, is a dynamic relationship between the destructive and reparative processes of the body. For example, some of the patients had aseptic necrosis of the femoral head with less than 1 microgram of radium, while others, with 10 micrograms or more, had no deleterious effects. It is reasonable to assume that these patients had other disturbances in the femoral head, such as an unsatisfactory blood supply. Another example of this dynamic relationship was demonstrated in the patient who had increased changes during pregnancy which subsided with the delivery of the child. Still another possibility is that certain periods of increased bone destruction or reduced bone formation may occur from disease processes which later revert to normal. One patient had rather severe changes in the mandible which later subsided.

D. Bone tumors

The 15 malignant tumors which developed in the 78 patients recently evaluated were found in individuals containing for 0.5 to 10 micrograms of radium in their bodies.[5] The patient having 0.5 microgram of radium was a luminous-dial worker. (It is reasonable to assume this patient ingested mesothorium and radiothorium.) The patient with the lowest radium concentration, who had received radium medically, had 0.9 microgram of radium. The patient with the lowest concentration of radium, which was considered not to be contaminated with members of the thorium decay series, and who developed a bone tumor, had 3.6 micrograms of retained radium. The accumulated radiation dose with 3.6 micrograms of radium was estimated to be about 5,000 rads during the 25 years from radium administration until tumor formation.[6]

---

[3] One patient which was evaluated later with 0.15 microgram of radium had dental changes.

[4] Symptoms is a term used to denote subjective awareness of an abnormality. When skeletal changes progress to such a degree that destruction of the hip or fractures occur—symptoms are noted by the patient.

[5] See fig. 14.

[6] The estimates of continuous radiation dose is based on the assumption that 0.1 microgram of total body radium will deliver a dose of 3 rads per year to the skeleton. It was found in the radium excretion studies made in the Chicago investigations that the retention of radium could be expressed as an approximate power function of time (27). From this information Brues and Tyler derived an expression for the estimation of the cumulative radium dose from the estimation of the instantaneous dose rate at the time of measurement. Based on the equation of Brues and Tyler, the total cumulative dose would be approximately twice the dose estimated at the time of measurement.

Only 2 bone tumors have developed in the 52 of the 78 patients who were not discovered because of symptoms arising from the skeleton. The frequency of bone tumors in this group is 2 percent, in contrast to a frequency of 14 percent for the entire group of 78 patients.

Vaughan (45) (1956) reported 39 cases of sarcoma arising in bone following external radiation have been recorded in the literature. The latent period between receiving radiation and the development of the tumor was 3 to 11 years. The radiation dose was not known in all of these cases; however, in most recorded cases it was estimated to be usually greater than 3,000 roentgen (1,500–7,000 roentgen change).

Cruz et al (10) (1957) reported an additional series of 11 cases in which the sarcoma of bone occurred from 4 to 24 years after external radiation. The total radiation dose given ranged from about 1,000 roentgens to 5,000 roentgens, and was given over a period varying from 1 month to 9 years.

COMMENTS ON THE POSSIBILITY OF BONE TUMOR FORMATION FROM STRONTIUM 90

The assumption is often made that the incidence of the effect of strontium 90 is proportional to the magnitude of the dose. This assumption has been used to estimate the bone tumors which may be produced from the low concentrations of strontium 90 in the skeleton from fallout. There is no exact evidence either proving or disproving this assumption, but there is some clinical evidence which suggests that this assumption is over cautious.

The 50 bone tumors which have been known to have been produced in man, and reported, were summarized in the previous section. The skeleton in the localized area of tumor induction received at least 1,000 roentgens, and usually more than 3,000 roentgens of radiation. If it is assumed that the radiation dose to bone is greater by a factor of 2 than the measured skin dose, then the minimum observed carcinogenic dose from external radiation would be about 2,000 rads, with the majority of the tumors being produced by more than 6,000 rads of external radiation.

The patient with the smallest total body radium known to induce tumor formation, in which the possibility of contamination of the thorium series in unknown, died from a bone tumor in 1952. The estimated total body radium was 0.9 microgram. The time after administration is unknown, however, it is reasonable to assume that it was about 25 years. Based on the estimates above, the patient would have received a total accumulated dose of about 1,800 rads during the 25-year period.

Histopathological changes have been demonstrated by roentgenographic examination of the skeletons of radium patients prior to development of the tumors. It is generally considered that the bone tumors develop in or around areas of atypical osseous tissue formation. Bone tumors have been shown to develop in or around the abnormal bone formation in animals given plutonium (22). If it could be shown that these histopathological changes are preliminary steps to bone tumor formation, then it could be assumed that as long as the body reparative processes prevented the abnormal bone formation, bone tumors would not develop. It should be emphasized that the associated histopathological changes seen prior to bone tumor formation in the radium patients may be coincidental findings. Proof of a correlation must await a better understanding of tumor induction by radiation.

In reviewing the latent period for tumor induction in the luminous-dial workers reported by Martland in 1931 (31), it was found that the latent period for tumor formation was about 5 to 10 years in 6 patients in this study who developed tumors. Only 3 of these patients had estimates of total body radium reported and these estimates were 6, 15 and 50 micrograms. (See table II.)

The eight luminous-dial workers who were examined in the recent Boston-Chicago investigations, and who died from bone tumors, lived for an average of 25 years after beginning employment. The average total body radium was 3.4 micrograms (range of 0.5 to 10 micrograms).

It is considered that little reliance can be placed in estimating the minimum total body content for tumor induction over a life span from this meager data. However, if we do estimate the total body radium which would have a latent period for tumor induction greater than the average life expectancy (80 years)

from the 2 average radiation doses and latent periods given above, it would be 0.3 and 0.4 micrograms of radium respectively.[7]

If we assume that 0.5 micrograms of radium retained for 70 years would be the minimal body burden necessary to cause skeletal sarcoma, this would mean that a cumulative radiation dose of about 2,000 rads would be necessary to induce tumor formation. It is considered that the most reliable estimates of the radiation dose necessary to induce bone tumors over a life span of 70 years, should be equivalent to the total radiation dose necessary to induce carcinogenesis in 5 to 30 years (2,000 rads). Therefore, the estimates of the total radiation dose from strontium 90 necessary to cause bone tumor formation in man during a life span of 70 years will be based on the best available estimates from human data of about 2,000 rads. It may be calculated that 1×10^{-9} curies of strontium 90 will give a radiation dose to the skeleton of 3 millirads per year, or 0.2 rads in 70 years under equilibrium conditions. Based on the preceding assumptions, the total skeletal radiation dose from 1×10^{-9} curies of strontium 90 over a 70-year period would be in the order of one ten-thousandths total skeletal radiation dose known to produce tumors in man, either from external or internal radiation.

COMMENTS ON THE PRESENT MPC OF RADIUM

Results of the Boston-Chicago investigations have shown that clinical changes begin to occur in patients with 0.4 micrograms of radium. The fact that changes are found to occur in man with 4 times the present MPC of 0.1 microgram of radium instead of 12 times the MPC when it was established in 1941, is offset by the greater confidence in the MPC by the studies of a much larger group of patients with radium present in their bodies for longer periods of time.

It is reassuring that it has not yet been necessary to change the MPC of radium of 0.1 micrograms following the large amount of information that has accumulated since it was first established. There are certain considerations, which, if sufficient information becomes available, may permit raising, or may necessitate lowering, the present MPC. These are as follows:

A. Factors which may permit the raising of the MPC for radium

1. The contribution of the thorium series to the dose from radium.—It is well established that mesothorium I (half life 6.7 years) and radiothorium (half life 1.9 years) were used in the luminous-dial paints, and mesothorium has been found in patients given radium medically. The radiation dose from mesothorium in some of these patients has been significant. It has been the major source of the cumulative radiation dose in some of the luminous-dial workers.

The time relation in this question is very important. It is assumed that reversible changes are produced by the presence of mesothorium, then its major clinical effect should have occurred before the changes began to occur in these patients. Roentgenographic changes do not begin to occur until 15 to 30 years after the deposition of the radioactive elements. However, once changes begin to develop in these patients, there is usually a gradual increase in the frequency and severity rather than a decrease. If the changes produced during the period immediately after deposition are irreversible and contribute significantly to the changes that are being seen in these patients 20 to 30 years later, then it may be possible to elevate the MPC. Further work is in progress in an attempt to clarify the relationship of mesothorium, radiothorium, and radium in the clinical changes observed.

2. Controls.—Even though the roentgenographic changes found in these patients are characteristic of radium deposition, further control studies to estimate more reliably the incidence of these changes in the general population should be carried out. The skeletal roentgenographic findings may eventually prove to be the most reliable method for the early detection of clinical changes from the deposition of bone-seeking radioelements. A better definition of the normal limits of skeletal variation is needed, in order that a more precise evaluation of the skeletal changes in the radium patients may be made.

The destruction of the head of the femur is another clinical finding in these patients which emphasized the need for further control studies; 11 of the 78 patients had destruction of the hip. This frequency of aseptic necrosis is

---

[7] These estimates are consistent with the findings of animal data of Brues[6], in which the latent period was found to vary inversely with the square root of the dose. The value of 0.3 micrograms of radium is obtained from assuming that the latent period of 10 years is increased by a factor of 8, and the average radium content is 25 micrograms. The value of 0.4 micrograms is obtained from assuming that the 25 years' latent period is increased by a factor of 3, and the average radium content of the patient is 3.4 micrograms.

unusually high in the absence of a history of antecedent trauma. Proper evaluation of this condition in the radium patients must await a better understanding of the cause of aseptic necrosis, as well as more reliable information as to its occurrence in the general population.

B. Factors which may necessitate lowering the MPC of radium

1. Age at the time of administration and duration of retention of radium.—The average age of the 50 patients at the time they received radium medically was 34 years. The average age of the luminous-dial worker at the time of employment was 17 years. Almost all of these patients either received radium, or were exposed to radium from 1920 to 1930. It is evident that the clinical information on the effects of radium deposited in the body for more than 40 years is lacking. Since the findings of the recent investigations suggest that clinical changes are the result of an imbalance between reparative and destructive processes of the body, it may be found that small amounts of radium in persons of the older age groups may produce significant clinical changes. This may result from either diminished reparative abilities, or an increase in skeletal destruction from other debilitating diseases of the older age groups.

There are only a few patients available for study of the long-term effects of radium who received the radium before the age of 15 to 20 years. One of these patients had the smallest amount of total body radium in which dental change characteristic of radium deposition has been observed.

The problem of bone tumor production in the younger age groups is probably the most important question in this regard. The greatest incidence of osteogenic sarcoma is considered to occur in the second and third decades, and almost no clinical information is available on the effects of skeletal radium deposition before this increase in the incidence of bone sarcoma occurs. It is possible that the increased susceptibility to skeletal tumor induction might necessitate a significant lowering of the MPC for children.

2. Undected subclinical effects.—The present philosophy for the establishment of the MPC is based on the correlation of physical estimates of the quantity of the radioelement in the body with detectable clinical changes or abnormalities in clinical tests. As more refined tests are developed to detect abnormalities in body function, it may be discovered that the present MPC is producing changes which are not detected by present methods of clinical evaluation.

Another important consideration is that subclinical changes may cause a reduction in the reserve function of organs. This may go undetected in most instances. However, the combined effects of an intercurrent disease and the reduced function from the effects of radiation may cause more severe effects than either the disease or the radiation separately.

COMMENTS ON THE PRESENT MPC OF STRONTIUM 90 BASED ON THE INFORMATION GAINED FROM THE EFFECTS OF RADIUM IN MAN

The present estimates of the MPC of strontium 90 are based on the assumption that both radium and strontium are distributed in a similar manner in bone. It has been shown that the radium concentration in different parts of the skeletons of the radium patients and luminous-dial workers may vary by a factor of 10 and probably greater. The present MPC for strontium 90 is based on the comparison of the average skeletal does of strontium and radium. Since under equilibrium conditions the strontium 90 distribution would tend to approach uniformity, comparison of the maximum skeletal dose in the localized areas of high radium concentration in the radium patients and the maximum skeletal dose in the strontium 90 patients might permit raising of the present MPC of strontium 90 by as much as a factor of 10.

The best available estimates indicate that biological effectiveness of radium is 1 to 4 times that of strontium 90 (i. e., the radium RBE[8] = 1 to 4) when compared on an equivalent energy basis. This work is based on the results of animal experimentation (15, 16). Comparison of the radiation dose necessary to produce bone tumors in man from internal and external radiation indicates that the RBE of radium may be somewhat nearer to unity. However, the estimation of radiation dose from external radiation might be in error by as much as a factor of 2. If it can be established that the RBE of radium is greater than unity then it might be possible to increase the MPC of strontium 90 by as much as a factor of 4.

[8] Relative biological effectiveness: The ratio of gamma of X-ray dose to the dose that is required to produce the same biological effect by the radiation in question.

It is considered that the best estimates that can be made in regard to the effects of strontium 90 over a life span (70 years) on the present incomplete information of the effects of radium in man are as follows:

1. The skeletal content of strontium 90 necessary to produce a bone tumor in a life span of 70 years would be in the order of 10 microcuries (100 times the present MPC of 0.1 microcurie of strontium 90 for the general population).

2. The skeletal content of strontium 90 necessary to produce significant changes, such as destruction of the hip, would also be in the order of 10 microcuries (100 times the present MPC of strontium 90).

3. The skeletal content of strontium 90 necessary to produce minimal skeletal changes which could be demonstrated roentgenographically, would be in the order of 2 microcuries (20 times the present MPC of strontium 90).

It should be emphasized that these estimates of the concentrations of strontium 90 which may produce skeletal damage are the result of estimates based on the best available information at present.

TABLE I.—*Age and sex distribution of 32 patients having between 0.5 and 14 micrograms of radium present in their bodies on an average of 21 years after deposition*

	Group I (0.5 to 1 microgram)	Group II (1 to 2 micrograms)	Group III (2 to 14 micrograms)	Total
Sex:				
Male	4	2	5	11
Female	11	6	4	21
Total	15	8	9	32
Age:				
30 to 40	1	0	0	1
40 to 50	9	4	2	15
50 to 60	3	3	2	8
60 to 70	0	0	3	3
70 to 80	2	1	2	5
Average age (years)	49	51.9	60.9	
Average time (years) since administration	20.3	22.2	22	

CHART I

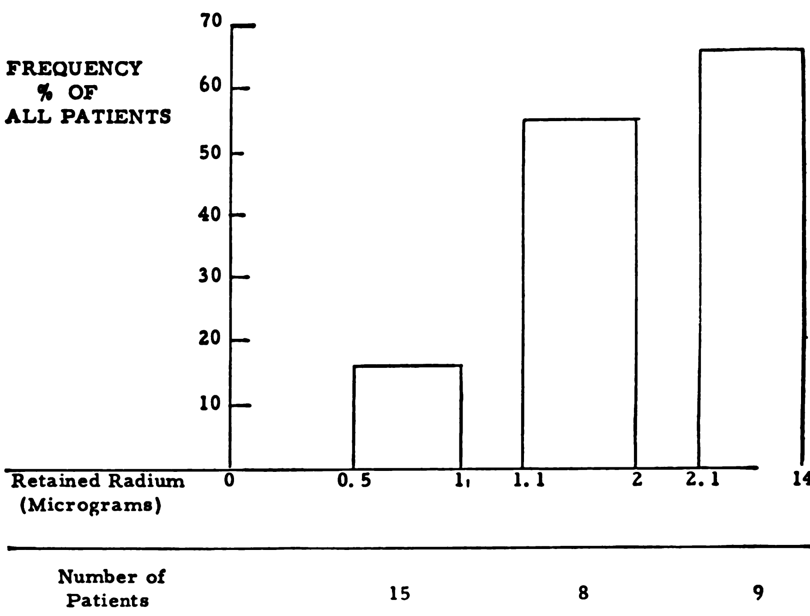

Table II.—*Time interval between deposition of radio-elements and occurrence of symptoms, tumor formation, and death in the 1931 and 1951 investigations*

	Number of patients	Average age at administration (years)	Average time from administration to death (years)	Average retained radium (micrograms)
Luminous-dial patients	3	17	10	23
1931 series				(6–50)
Range, years		16–21		
Luminous-dial patients	8	17	26	3.4
1951 series				(.5–10)
Range, years		15–21		
Radium patients		39	26	3.1
1951 series	5			(.8–8)
Range, years		25–49	1–8	

Figure 1

CHANGE OF ELIMINATION COEFFICIENT WITH TIME

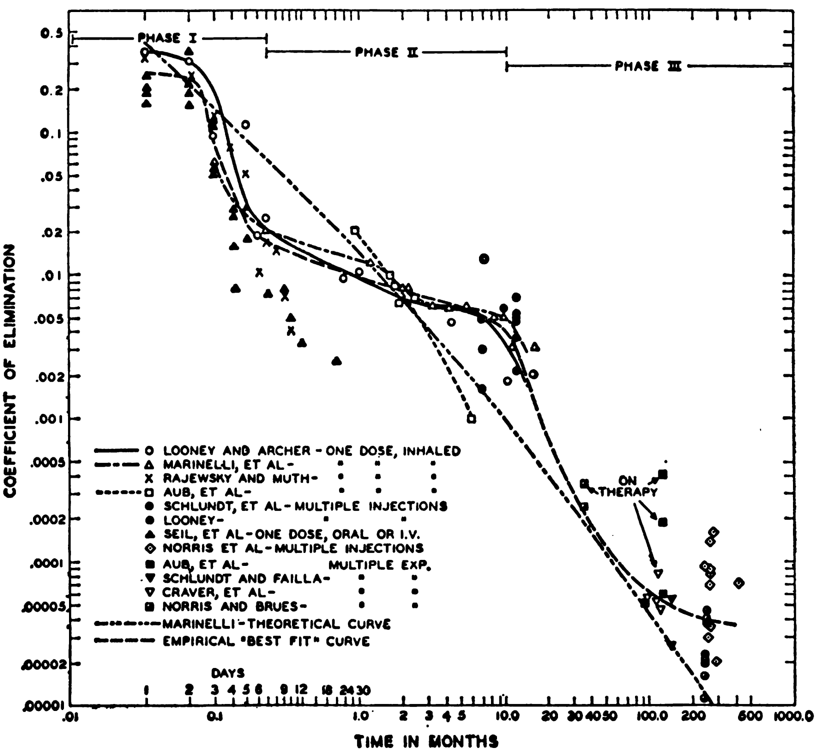

FIGURE 2.—Gross autoradiogram of a longitudinal section of the femur of patient M. K. Note the irregular distribution of radium in the cancellous bone of the upper end of the femur and the small areas of focal concentration in the cortex. The contour of the head is outlined by small concentrations at the junction of the articular cartilage and cancellous bone. The medial portion of the shaft is outlined by the small highly concentrated areas near the periosteum and the endosteum. (Reproduced courtesy of Journal of Bone and Joint Surgery.)

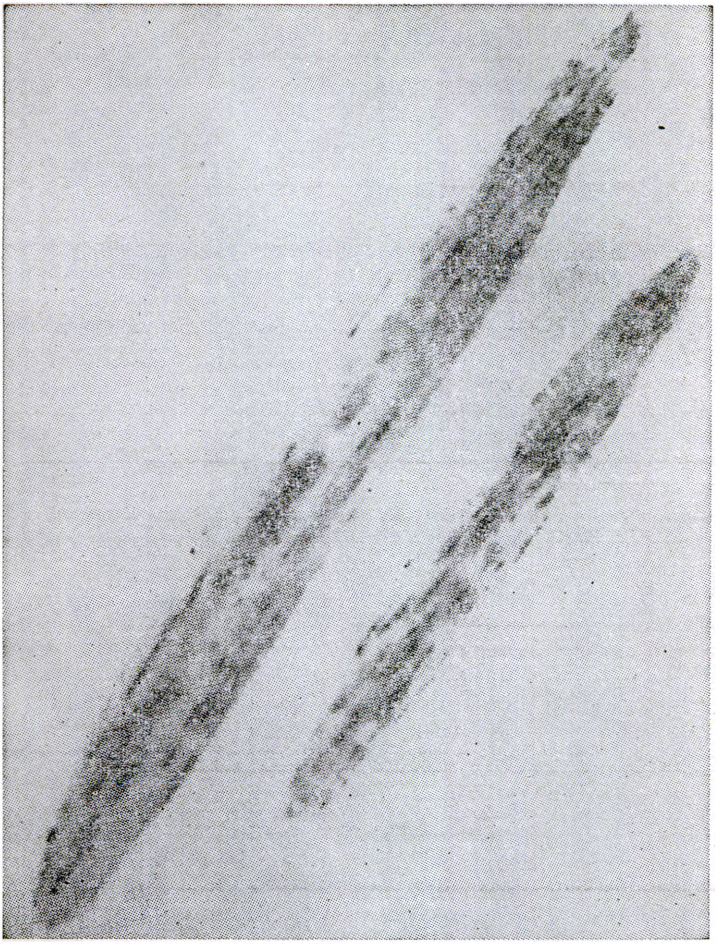

FIGURE 3.—Gross autoradiograms of two longitudinal sections of the cortex of a femur from patient R–24 (5-week exposure). Smaller section was taken 2 millimeters from the periosteum and the larger section was cut just medial to it. Areas of concentration are more frequent in the smaller section and the lower end of the larger section, which are nearer periosteum. The large area of darkening in the center of the larger section is the result, probably, of an endosteal concentration of radium, since this section was on the periphery of the narrow cavity. (Reproduced courtesy of American Medical Association, Archives of Pathology.)

FIGURE 4.—Detailed autoradiogram of a cross section of cortical bone from the humeral shaft of patient R–24 (5-week exposure). Two of the small number of Haversian systems have radium concentrated in this section. The greatest concentration of radium is on two concentric lamellae in the center of the Haversian system. Alpha tracks are less dense in remainder of the two Haversian systems and interstitial lamellae between the systems. Observe that the activity suddenly falls off around these areas of concentration and that the rest of the photomicrograph is free of alpha tracks (X 207). (Reproduced courtesy of American Medical Association, Archives of Pathology.)

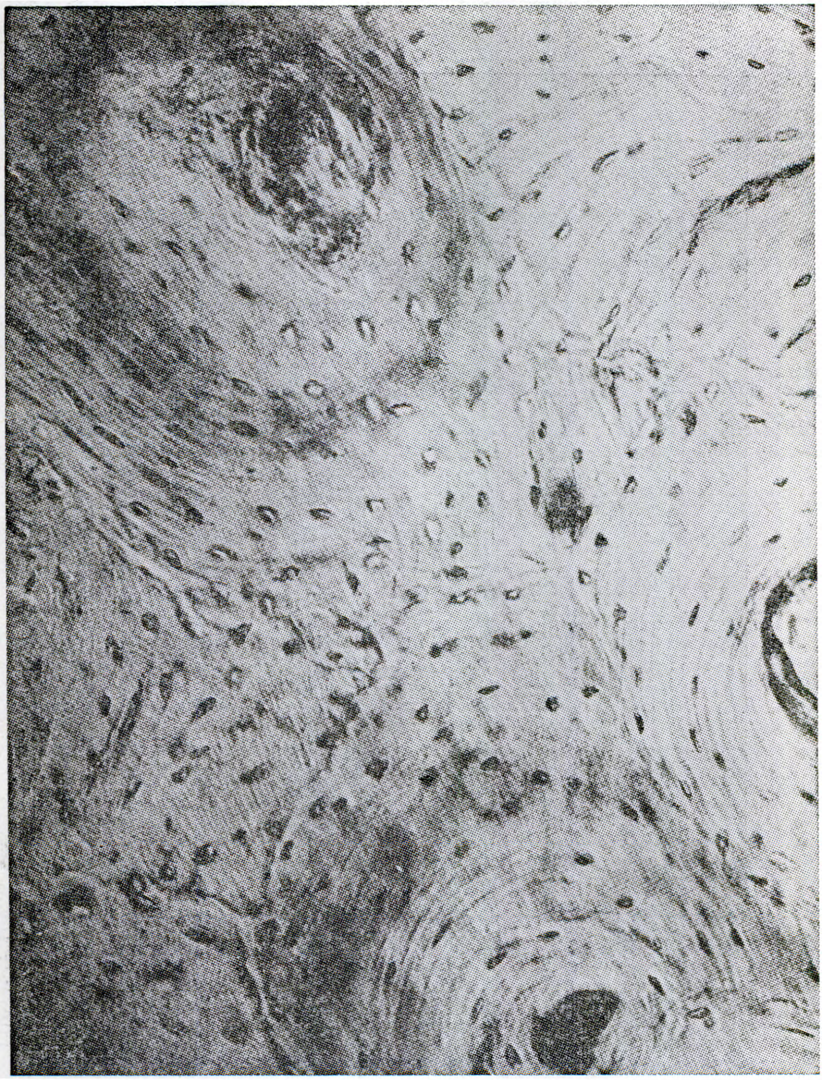

FIGURE 5.—Photomicrograph of bone underlying detailed autoradiogram shown in Figure 4. Note the dark concentric rings outlining lamellae with greater concentration of radium. Central part of Haversian system in upper left is undergoing destructive changes. This, together with figure 4, demonstrates how radium concentration and histopathological changes can be studied at the same time (X 218). (Reproduced courtesy of American Medical Association, Archives of Pathology.)

FIGURE 6.—Histological section of the head of a right humerus (fig. 2). Note the areas of atypical osseous tissue throughout the head. The largest area of atypical osseous tissue is seen at the top of the photograph near the articular surface. (Reproduced courtesy of Journal of Bone and Joint Surgery.)

FIGURE 7.—Photomicrograph of one of the areas of atypical osseous tissue seen in the histological sections. The atypical osseous tissue is seen at the top of the photograph. The acellular fibrous tissue is seen throughout the trabecular spaces. (Reproduced courtesy of Journal of Bone and Joint Surgery.)

FIGURE 8.—Higher magnification of one of the areas seen in figure 4. Bone is seen in the lower left corner, with darker staining atypical osseous tissue adjacent to it. Fibrous connective tissue is seen in the remainder of the field. (Reproduced courtesy of Journal of Bone and Joint Surgery.)

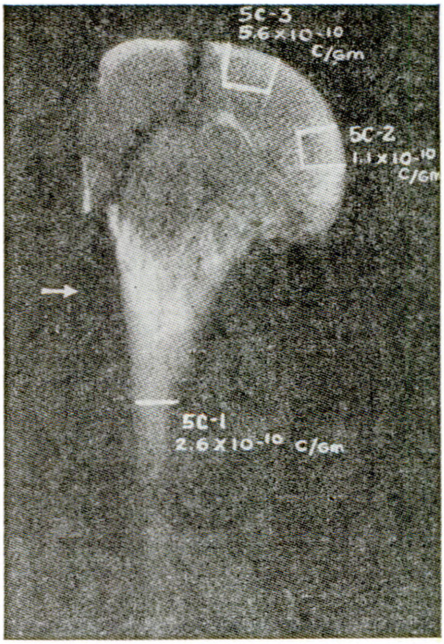

FIGURE 9.—Roentgenogram of a 2-millimeter section taken from the head of the right humerus. (See fig. 6.) Sections of bone, 5C–2 and 5C–3 were removed following the making of gross autoradiographs of this bone section. As will be noted in the figure, 5C–2 was taken from an area which seemed to have a large concentration of radium as shown by gross autoradiography; 5C–3 was taken from an area which seemed to have a small amount of radium as shown by gross autoradiography and a normal roentgenographic pattern. It should be noted that the radium content in RC–3 was five times the content in RC–2. Radium values are expressed as curies per gram of ashed bone. (Reproduced courtesy of the Journal of Bone and Joint Surgery.)

FIGURE 10.—Roentgenogram of the head of the femur of patient (R–34). The mottled appearance is the result of the atypical osseous tissue and hypertrophy of the trabeculae and is characteristic of the changes seen in cancellous bone following the deposition of radioactive elements (Review figs. 6, 7, 8, and 9). (Reproduced courtesy of Journal of Bone and Joint Surgery.)

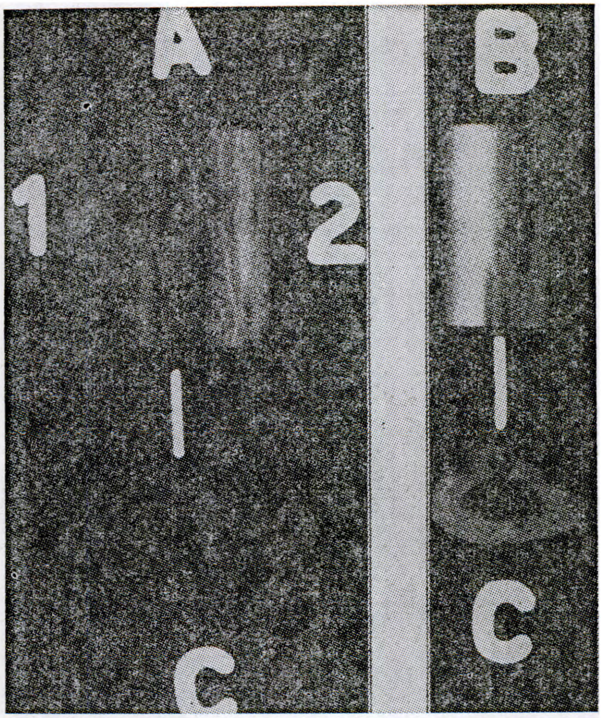

FIGURE 11.—Roentgenogram of a horizontal and vertical section of the fibula of patient (R-24). Note the "streaked" areas that are seen in the long bones as the result of well differentiated areas of destruction in the cortex. The pointers show the areas of destruction in the vertical and horizontal planes (Argonne National Laboratory Report, ANL 4666).

FIGURE 12.—Photograph of the areas of destruction seen in figure 11B. Note that the areas of destruction which give a "streaked" appearance to the long bones are about 3 to 6 times the diameter of the Haversian systems. The central canal in between the two macroscopic areas of destruction is about one-third the diameter of the Haversian system, while in the upper right corner there is a central canal that is enlarged to about two-thirds the diameter of the Haversian system (Argonne National Laboratory Report, ANL 4666).

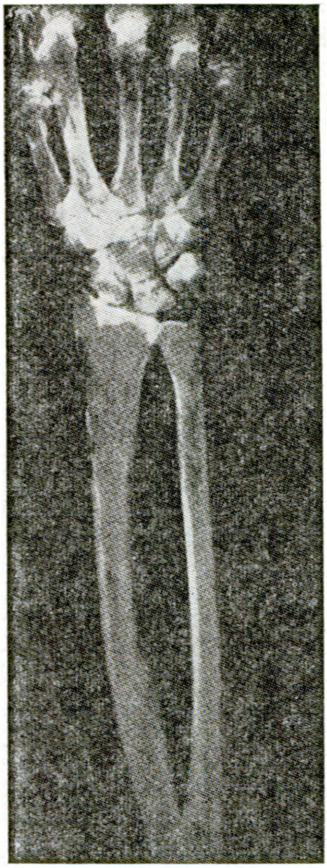

FIGURE 13.—Roentgenogram of the lower arm and hand of patient M. L. (L–27). The small areas of decreased density in the radius and ulna and bones of the hand give a streaked appearance. These small well differentiated areas of decreased density are characteristic of the deposition of radioactive elements. (Reproduced courtesy of American Journal of Roentgenology, Radium Therapy and Nuclear Medicine, 72 : 842, 1954.)

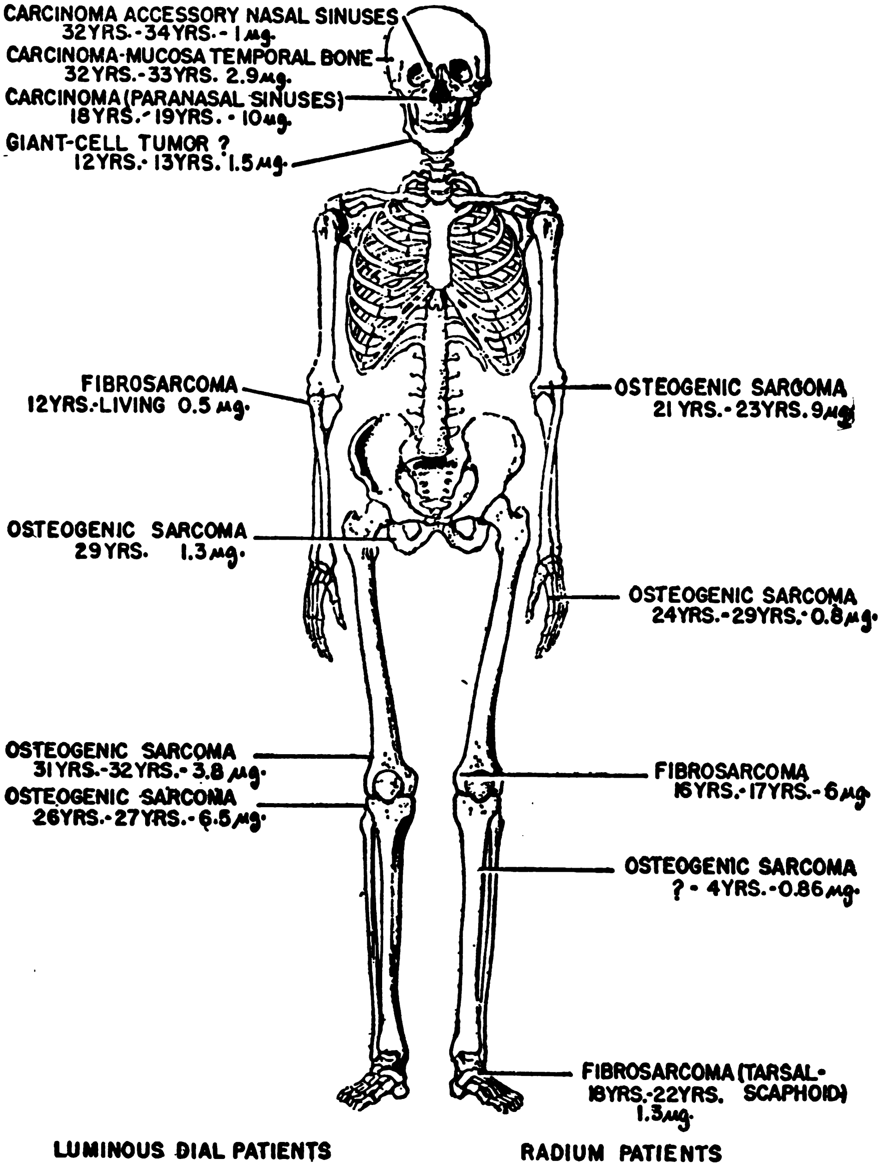

FIGURE 14.—Tumor formation in patients in Boston and Chicago investigations (1951). The five tumors which developed in the 50 patients who had received radium are shown on the right side of the skeleton and the 8 tumors which developed in 8 luminous-dial painters are shown on the left side of the skeleton. Two more tumors have developed in the patients who had received radium medically. These are not included. The type of tumor, the time from deposition to occurrence of symptoms, the time from deposition to death, and the amount of radium are given in each case. Reading from top to bottom, the numbers of the luminous-dial workers are 15, 20, 25, 16, 8, 14, 21, and 23; the numbers of the radium patients are 45, 17, 36, 18, and 24. (Reproduced courtesy of Journal of Bone and Joint Surgery.)

ACKNOWLEDGMENTS

The author wishes to express his appreciation to Dr. William Rogers, editor of the Journal of Bone and Joint Surgery, Dr. Lawrence Reynolds, editor of the American Journal of Roentgenology, Radium Therapy and Nuclear Medicine, and to Dr. Paul Cannon, editor of the American Medical Association Archives of Pathology for granting permission to incorporate results of investigations published in their respective journals in this report.

From 1950 to 1952, the author was a postdoctorate Atomic Energy Commission fellow in the medical sciences of the National Research Council at the Argonne National Laboratory. He was assigned the responsibility for the clinical aspects of the investigation of individuals who had been given radium salts and people who had been employed as luminous-dial workers (1915 to 1930) and the responsibility for the correlation of the clinical aspects with the biophysical aspects of the investigation. This investigation was conducted by the following: Dr. A. M. Brues, Dr. L. D. Marinelli, Dr. W. P. Norris, Dr. R. J. Hasterlik, and Dr. A. H. Stehney, their associates and the author. The histopathological studies were made at the department of orthopedic surgery, University of Chicago, with Dr. C. Howard Hatcher. Detailed reports of the various phases of the investigation will be published.

The author was afforded the privilege of reviewing the clinical data of a similar investigation carried out at the Harvard Medical School and the Massachusetts Institute of Technology by Dr. J. C. Aub, Dr. R. D. Evans, Dr. L. H. Hempelmann, and Dr. M. S. Martland.

The Atomic Energy Commission fellowship, 1950–52, was under Dr. A. M. Brues, Director, Division of Biology and Medicine, Argonne National Laboratory.

Dr. L. D. Marinelli, Dr. W. P. Norris, Dr. A. H. Stehney, and their associates were responsible for the physical and radiochemical aspects of the investigation at the Argonne National Laboratory.

Dr. R. J. Hasterlik and Miss Ellen Shermont gave their assistance in the clinical and hematological aspects of the investigation at the Argonne National Laboratory.

Dr. Joseph Aub, Dr. Robley Evans, Dr. Louis Hempelmann, and Dr. Lawrence Robbins gave their assistance in the review of the clinical data of the investigation carried out at the Harvard Medical School at the Massachusetts Institute of Technology.

The late Dr. Dallas Phemister and Dr. C. Howard Hatcher of the University of Chicago gave their assistance in the orthopedic and histopathological aspects of the investigation.

Dr. Granville Bennett of the University of Illinois, Dr. Lent Johnson of the Armed Forces Institute of Pathology, and Dr. J. A. Turner of the Naval Medical School gave their assistance in the histopathological aspects of the investigation.

Dr. William Bloom and Dr. Franklin C. McClean of the University of Chicago gave their assistance in the histopathological aspects of the investigation.

Dr. James Arnold and Miss Lois Woodruff gave their assistance in the autoradiographic aspects of the investigation.

Dr. Paul C. Hodges and Dr. Russell Nichols of the University of Chicago and Dr. Robert Potter of Northwestern University gave their assistance in the radiological aspects of the investigation.

Dr. Edward Jerome of the Naval Medical Research Institute, and Mr. Sylvanus Tyler and Miss Joan Guerin of the Argonne National Laboratory gave their assistance in the statistical aspects of these investigations.

Dr. V. E. Archer of the National Institutes of Health gave his assistance in the preparation of the data on the elimination of radium.

Mr. Atlee Tracy of the Argonne National Laboratory and Mr. J. T. Stringer of the Naval Medical School were responsible for the photographs.

Mr. Melvin Runkel of the Naval Medical School and Miss Frances Fee of the Argonne National Laboratory prepared the illustrations.

A Study of the Dynamics of Strontium and Calcium Metabolism and Radioelement Removal [1]

PRELIMINARY REPORT, MAY 31, 1957

W. B. Looney,[2] C. J. Maletskos,[3] M. J. Helmick,[4] J. Reardon,[5] J. Cohen,[6] W. Guild,[7] and F. I. Visalli [4]

The classic studies of Aub, Evans et al.[1a] in 1938 in radioelement removal demonstrated that the renal clearance for radium was less than 1 percent in 24 hours. This finding suggested the possibility that direct radioelement removal from the blood might prove to be an effective way of eliminating radio-

elements. Both the artificial kidney[2] and ion-exchange resins[3] afford means for radioelement removal, as well as providing an opportunity for extension of the work by Hastings and Huggins[4] on the mobilization of calcium in the circulating body fluids.

Preliminary in vitro experiments were performed to determine some of the parameters necessary to evaluate the feasibility of using either approach.

The first experiments were carried out on a simulated artificial kidney. Stable calcium, calcium 45, and ethylenediamine-tetraacetic acid were readily dialyzable under conditions similar to those in the artificial kidney (calcium being omitted for the purpose of the present experiments).[5]

In later experiments solutions of strontium 85 and calcium 45 were passed directly through ion-exchange columns to determine the effectiveness of a synthetic cation exchange resin in removing radioelements.

A total of 20 dogs has been studied, each dog having been connected to either the artificial kidney or ion-exchange column following the administration of strontium 85, strontium 89, and calcium 45. The ion-exchange column has been used in preference to the artificial kidney because of its more effective removal of calcium, its simplicity and potential adoption for more extensive utilization.

The ion-exchange resin offers a wide range of potential application to biological investigation. Appropriate adjustment of the cation concentrations in the column permits preferential removal of a particular cation of interest. The ability to place electrolytes of a biological system out of equilibrium affords an excellent tool for the study of the dynamics of both the stable and the radioactive electrolytes of the biological system.

The efficiency of radioelement removal as a function of time after administration has been determined by both single- and multiple-isotope methods. Between 30–40 percent of the radio-isotopes injected intravenously 1 hour prior to connecting the dog to the resin column can be removed during a 4- to 6-hour period. At 12 hours after injection, total removal of the radioelements decreased to about 6 to 12 percent, and at 24 hours to about 3 to 6 percent. After 3 days about 2 percent is removed. When the experiment was repeated in 2 dogs 1 week later, less than 1 percent was removed.

Analysis of the removal of the isotopes in three dogs indicated the following: About 80 to 90 percent of the dose is in a hypothetical compartment of bone which has a half time of removal of 8 to 16 hours; the remainder of the dose is in a compartment approximating in size the extracellular space and the half time of removal is 15 to 30 minutes.

To test the influence of serum calcium concentration on isotope removal, calcium 40 was infused intravenously at the same time as the resin perfusion. No significant decrease in radiostrontium removal has been found in 2 dogs in which the serium calcium levels of 6 to 8 milligrams percent were maintained. This result would be consistent with the hypothesis that the principal mechanism of radioelement removal by the ion-exchange column is cation exchange rather than enhanced physiological response from depressed calcium levels.

These studies demonstrate that the ion-exchange column and the artificial kidney are practical means for studying the dynamics of stable and radioactive electrolytes. No major contraindications have been found to prevent its adoption for clinical use.

Representative COLE. Mr. Chairman, if you do not mind, I would like to ask again, Dr. Looney, if you will interpret your expression that the assumption that the incidence of the effect of strontium 90 is proportionate to the magnitude of the dose. You have indicated that experience and studies led you to the conclusion that this is an overcautious—did you say overcautious?

Dr. LOONEY. Yes.

[5] Looney, W. B., Maletskos, C. J., and Helmick, M. J.: Removal of Radiocalcium in Dogs, Progress Report, Radioactivity Center, M. I. T., Department of Physics, May 1956.

Representative COLE. Assumption?

Dr. LOONEY. Yes.

Representative COLE. What do you mean by that?

Dr. LOONEY. I mean that the present clinical information that we have would not substantiate the concept of a linear relationship, neither does it disprove it. If I had to weigh and balance these two factors, I would say that most of the information indicates that a certain amount of irradiation is necessary to produce bone tumors in man. However, this is based on the available information. It certainly is to be again emphasized that these tumors may be produced in man at a lower dose, and we have not been able to detect this at present. There are some methods of obtaining more information from clinical studies. I think they will be done.

To say this might be an overcautious assumption is probably not a good term, but I hope I have given you the reason for making the statement.

Representative COLE. Since your clinical evidence indicates that the incidence may be less in proportion to the magnitude of the dose, would that indicate the possibility of a threshold for the effects of strontium 90?

Dr. LOONEY. I would say that the present clinical information in man would not substantiate either conclusion.

Representative COLE. Based on clinical evidence?

Dr. LOONEY. Based on the evidence in man; yes, sir.

Representative COLE. You are not able to determine yes or no with respect to threshold?

Dr. LOONEY. No, sir; I am not.

Representative HOLIFIELD. Dr. Looney, how were you able to determine the amount of exposure these people had, in view of the fact it was years later before you were aware of their illnesses?

Dr. LOONEY. The patients in Chicago were found by reviewing the records of a mental hospital in which the patients were given radium. The files of the United States Radium Corp. were also made available to the Argonne National Laboratory, and we were able to get names and to locate these people by following names.

Representative HOLIFIELD. This did not obtain to those employed as radium painters?

Dr. LOONEY. Yes; it did.

Representative HOLIFIELD. Were you able to measure the dose they received at the time they received it by the residual amount in their bones when it was called to your attention?

Dr. LOONEY. The physical estimates were made by the physicists at Massachusetts Institute of Technology, and at Argonne National Laboratory. That is a physical area, and I would prefer to leave it to the physicists.

Representative HOLIFIELD. I was just interested to find out if we had an accurate estimate of the original dose. I know in the case of the Hiroshima and Nagasaki people that is one of the missing elements in our evaluation of the dose, that we do not know exactly how much they have received.

Dr. LOONEY. Yes. In regard to the patients in the mental hospital, we do have a record of the amount given, and the estimates at 6 and 12 months. Estimates were also made after 20 years. This is the

best available evidence we have in man. Based on this information we can make estimates of the original dose of radium in other people in which we find the radium 20 to 30 years after administration. The physical data on the luminous dial workers is confused by the fact that mesothorium and radiothorium were present in the paint. This presents a very difficult problem in trying to establish reliably the relationship of the clinical changes to the physical estimates of the radiation dose.

Representative HOLIFIELD. Thank you.

Representative VAN ZANDT. Dr. Looney, is it possible to leach out selectively the poison that has gotten into the skeleton of the body?

Dr. LOONEY. You are talking about removal of these radio elements once they are deposited in bone?

Representative VAN ZANDT. Yes.

Dr. LOONEY. We have been working on that in Boston in the past 2 years, trying to remove strontium 85, strontium 89, and radio calcium from bone. We found in the first hour we can remove approximately 30 or 40 percent of the strontium. This efficiency of removal rapidly declined, until after 2 or 3 days, it was less than 1 percent.

Other methods using chemicals to remove bone-seeking radio element have been attempted. There has been some progress in this field, but once the radio element is deposited in the bone, the chances are very remote that we will be able to remove it.

Representative VAN ZANDT. Thank you.

Chairman DURHAM. Doctor, figure 14, where you have the skeleton——(See p. 1188.)

Dr. LOONEY. Yes, sir.

Chairman DURHAM. Was any conclusion made as to why the carcinoma was more prevalent in the head and nose and mouth than other parts of the body?

Dr. LOONEY. You will notice that these people who developed these tumors were luminous dial workers. There has been the hypothesis that because the material was ingested and inhaled, rather than injected intravenously or given orally, that it might be the result of the local effect. But, I might point out that one of the radium patients has also developed a similar type of tumor. I have no readily available conclusion as to why this developed.

Senator HICKENLOOPER. Mr. Chairman.

Representative HOLIFIELD. Senator Hickenlooper.

Senator HICKENLOOPER. Just from a visual examination of the chart, it would indicate that one might assume the tumors occurred in proximity to the point of contact or ingestion of this radium treatment, or the radium material. In other words, with the luminous dial patients, as I understand it, they ingested this as a result of either inhalation or putting the brushes in their mouths to wet them so they could point them up and paint the figures on the dials.

Dr. LOONEY. Yes, sir; that is correct.

Senator HICKENLOOPER. And the incidence seems to be much greater in the nasal and throat area in those. On this chart there is no incidence of a tumor above the elbow in the strictly radium patient as differentiated from the luminous dial patient.

Dr. LOONEY. Yes. However, you will note it is a different type of tumor in the radium patients. You will notice these tumors are carcinomas in the luminous dial workers, and you will notice that the

sacromas of bone have occurred both in the luminous dial workers and radium patients.

Senator HICKENLOOPER. I am speaking purely as a layman who knows nothing whatsoever about this thing. A layman might be led to the conclusion from the chart that radium treatments might have been given in other parts of the body, but in the luminous dial workers the repeated incidence is at the point of ingestion very frequently.

Dr. LOONEY. This is an interesting observation, sir. I know this has created considerable comment as to whether there is a casual relationship among the people associated with these investigations. I am trying to point out both arguments for and against this. It is a different type of tumor that has developed in his area, and most of the tumors have been sarcomas of the bone.

Chairman DURHAM. Did the same type rays produce the three different types of sarcomas and carcinoma? You have three different types. Did the same rays produce all three types?

Dr. LOONEY. I think that the present available evidence is that any radiation has a similar effect biologically. So that it would be a combination of these three effects.

As far as radium is concerned, the majority of the radiation comes from the alpha particles, probably 90 or 95 percent.

Chairman DURHAM. Then the conclusion would be that beta rays or gamma rays would produce all types of carcinomas?

Dr. LOONEY. In sufficient quantities we must be aware of the quantitative aspects of the effect of radiation. I think it was brought out previously that the very sensitivity of physical measurements may lead to overemphasizing the effects of minute amounts of radioactivity.

We have a range of thousands of times between the amount of strontium 90 that is present, and the amount of strontium 90 that we calculate to produce equivalent energy to cause tumors in man from the available information on radium.

Representative VAN ZANDT. Mr. Chairman?

Representative HOLIFIELD. Mr. Van Zandt.

Representative VAN ZANDT. Dr. Looney, you have been talking about bone tumors. What about the utilization of radiation to attack these bone tumors?

Dr. LOONEY. Well, sir, I am not a radiologist, and this is in the field of radiology. I am aware of this, but I think you would get a much more competent opinion on this from some radiologist who is actively engaged in treatment.

Representative VAN ZANDT. Would the same thing apply to arthritis?

Dr. LOONEY. Yes, sir.

Representative VAN ZANDT. One more question, Dr. Looney. You have had many years of experience now in studying the body that has absorbed radiation from radium. Have you developed any kind of a preventative to this type of radiation?

Dr. LOONEY. No, sir, we have not yet. So far as I know, there has been no effective means of treatment.

Representative VAN ZANDT. Have you developed any type of a program that would prepare the body to resist radiation stemming from radium?

93299°—57—pt. 2——13

Dr. LOONEY. I have no knowledge of such.

Representative HOLIFIELD. Thank you very much.

Our next witness will be Dr. W. F. Libby, Commissioner, Atomic Energy Commission, a distinguished chemist, and member of the Commission since 1954.

Dr. Libby, before you start your testimony, the Chair will insert, without objection, 2 letters of notification, 1 under date of May 3 to Mr. Strauss, which gave an outline of our hearings, and the witnesses that had been invited up to that time, and the second letter under date of May 21, which supplemented the first letter. I would like to read the pertinent part of that, in which I said to Mr. Strauss:

> I would like to make clear that we would be happy to have Dr. Libby on hand to provide extra testimony and comment throughout the hearings after the introductory witnesses beginning on Monday afternoon, May 26. We understand that he is preparing written statements for certain portions of the outline. We will be glad to receive these statements for the record, and will be happy to have Dr. Libby comment on them orally as each topic comes up.
>
> We would also appreciate hearing from Dr. Libby on topic 11, in which he could discuss the implication of our present knowledge of the fallout situation as it exists.

(The letters are as follows:)

CONGRESS OF THE UNITED STATES,
JOINT COMMITTEE ON ATOMIC ENERGY,
May 3, 1957.

Mr. LEWIS L. STRAUSS,
Chairman, United States Atomic Energy Commission,
Washington, D. C.

DEAR MR. STRAUSS: The Joint Committee on Atomic Energy plans to hold open hearings in Washington, D. C., on the subject "The Nature of Radioactive Fallout and Its Effects on Man," May 27–29 and June 3–7. This letter is to confirm arrangements made informally for representatives of the Commission and AEC laboratories to testify before the committee. It is our understanding that these arrangements have already been discussed at some length on an informal basis by our respective staffs.

We are attaching material covering the scope, approach, plan and outline of the hearings. You will note the planned division of the hearings into two parts: (I) an organized sequential presentation by expert witnesses, and (II) an open presentation by those working in the field or by interested members of the public who have asked for an opportunity to testify before the committee. You will also note that the outline gives guidance, by each topic I–XII, as to whether the presentation is planned as oral, written inserts for the record, or bibliography—or some combination of those. It is intended that witnesses use their own discretion as to the details of the presentation, and it is not necessary that the outline be rigidly followed. Points that the committee is particularly interested in may be developed by questioning of witnesses.

We are requesting the following representatives of the AEC to testify as expert witnesses for various parts of the organized sequential presentation:

Dr. Charles L. Dunham, Director, Division of Biology and Medicine, Topics I, XI, and XII.

Dr. Willard F. Libby, Topics IV, VI–C–4, IX (Sr–90), and XI.

Gen. A. D. Starbird, Director, Division of Military Application, topic V (General Starbird to be preceded by Dr. Bradbury, of LASL, and Dr. Shelton, of AFSWP).

Dr. Gordon M. Dunning, Division of Biology and Medicine, topic VII.

Dr. Merril Eisenbud, New York Operations Office, for topic VI–C–3 and VI–C–4 and topic III.

Dr. R. F. Reitemier, Division of Biology and Medicine, for a joint presentation of topic VIII, parts B, C, D, E, and G, with Dr. Lyle T. Alexander, of the Agriculture Department.

Dr. Forrest Western, Division of Biology and Medicine, for topic VIII, parts A and H, and perhaps to provide continuity for the other topics in

topic VIII. (The portions of VIII dealing with oceanography and marine life are planned for coverage by Dr. Roger Revelle, Scripps Institute.)

In addition, there is one topic, topic III, for which we would be glad to insert into the record any written statements the AEC would care to submit.

From the AEC laboratories, we are planning to invite the following persons to present oral or written testimony:

Dr. Mark Mills, UCRL, Livermore.
Dr. Wright Langham, LASL.
Dr. E. C. Anderson, LASL.
Dr. ——— Marinelli, ANL.
Dr. Austin Brues, ANL.
Dr. E. P. Cronkite, BNL.
Dr. Norris Bradbury, LASL.

These persons are being contacted directly.

It is possible that other persons in AEC or its laboratories will be needed or that changes in the planned presentation will develop. However, it is not expected that there will be major changes.

The Joint Committee would appreciate receiving as soon as possible short biographies of each person giving testimony, covering professional background, present work, home address and phone number, business address and phone number.

The Committee hopes that the forthcoming hearings will lead to a better understanding of a problem that has become the subject of serious concern to the Congress and the people of this country. Such understanding is essential, in the Committee's view, to the development of sound national policies and to the maintenance of good relations with our friends and allies throughout the world.

The cooperation of the AEC in contributing to the success of the hearings will be greatly appreciated.

Sincerely yours,

CHET HOLIFIELD,
Chairman, Special Subcommittee on Radiation.

CONGRESS OF THE UNITED STATES,
JOINT COMMITTEE ON ATOMIC ENERGY,
May 21, 1957.

Hon. LEWIS L. STRAUSS,
Chairman, Atomic Energy Commission,
Washington, D. C.

DEAR MR. STRAUSS: We are pleased to receive your May 17 letter offering to cooperate with us as we begin our radiation fallout hearings next Monday morning.

As you know from my May 3 letter, we plan that the first portion of the hearings, taking perhaps the days up to about Thursday, June 6, would be devoted to an organized sequential presentation by expert witnesses of the scientific subject matter related to fallout. This presentation would wind up with two topics concerned with the impact of the present state of affairs scientifically on national policy and on the research programs related to fallout.

The purpose of the presentation is primarily to educate the committee, the Congress, and the public on the scientific aspects of this important subject. The outline of this organized presentation, sent to you with my May 3 letter, was developed after consulting with various scientists to figure out the best way to present the subject matter fairly and impartially.

In line with the above arrangement, scientific witnesses were selected to present the subject matters. The list of witnesses and order of presentation was distributed last week. Dr. Dunham was selected to lead off with an objective presentation of the nature of the overall topic of the hearings: radiation and radioactivity, particularly fallout. He was chosen as a qualified represenative of AEC who happens not to have become publicly involved in controversy on the fallout question. It has been our aim to begin and carry on the hearings in a noncontroversial spirit.

My May 3 letter to you listed Dr. Libby as a desired expert witness for several topics, beginning with topic IV (natural background radioactivity) of the outline. We would be happy to have him come before the committee to present objective testimony on these topics. It has been our informal understanding

that Dr. Libby might prepare written statements for these topics but did not wish to appear personally as a witness except once, for a comprehensive statement. Accordingly, our latest timetable lists Dr. Libby only for topic XI (impact on policy), where he can cover any of the scientific facts and implications that he cares to.

Your cooperation and that of the AEC staff in assisting the committee with preparations for the fallout hearings is greatly appreciated.

Sincerely yours,

CHET HOLIFIELD,
Chairman, Special Subcommittee on Radiation.

Representative HOLLIFIELD. Dr. Libby, we are happy to have you before us, and we are ready for your statement.

STATEMENT OF DR. WILLARD F. LIBBY,[1] COMMISSIONER, ACCOMPANIED BY DR. CHARLES L. DUNHAM, DIRECTOR, DIVISION OF BIOLOGY AND MEDICINE, ATOMIC ENERGY COMMISSION

Dr. LIBBY. Mr. Chairman and members of the committee; it is a privilege to be present today because it gives me an opportunity to discuss with you this very important subject—one in which I have taken great personal interest, having spent a major part of my time in the last 4 years directly on this research—watching the progress, performing experiments, and making calculations. Excluding weapons, I consider Project Sunshine—the study of worldwide radioactive fallout and its effect on man—to be one of the most important projects the Commission has. The project is essential, if the Commission is to fulfill its responsibilities in protecting public health and safety. It is being conducted as a scientific study whose primary purpose is to discover the scientific truth and present the facts—publicly.

Senator ANDERSON. Before you go further, is this your own statement, or does this represent the views of the Atomic Energy Commission?

Dr. LIBBY. This is my own statement, Senator Anderson.

Senator ANDERSON. It has not been cleared?

Dr. LIBBY. I have asked for comment, but it is not an official statement of the Commission; it is my own statement.

Senator ANDERSON. Thank you. I thought that was important.

Dr. LIBBY. Yes.

Representative COLE. On that point, Mr. Chairman; you say you have asked for comments. I assume you meant you submitted your statement to other members of the Commission for their comments?

Dr. LIBBY. Yes.

Representative COLE. And have you received comments from any of the Commission?

Dr. LIBBY. There have been no substantial changes. I am not sure all of the Commissioners commented. I left it to my staff to collect the comments, and I am not just sure.

Representative COLE. Did you submit your statement to all of the Commissioners?

Dr. LIBBY. I believe so, sir; yes.

---

[1] Date and place of birth: December 17, 1908, Grand Valley, Colo. Education: Bachelor of science, University of California, 1931; doctor of philosophy (chemistry), University of California, 1933; Work history: Instructor of chemistry, University of California, 1933–38; assistant professor, 1939–43; associate professor, 1943–45; professor instructor nuclear studies, Chicago, 1945–54; member, General Advisory Commission, AEC, 1950–54; member AEC, 1954—. (Submitted by the Atomic Energy Commission.)

Representative COLE. Were there any of the Commissioners who did not respond or indicate a comment?

Dr. LIBBY. I will have to check with my staff on that.

Representative COLE. So far as you know?

Dr. LIBBY. I do not know of any.

Representative COLE. One more question at that point: How long previous to this morning did you submit the statement?

Dr. LIBBY. It was about a week ago, as I recall, Mr. Cole.

Representative COLE. Thank you.

Dr. LIBBY. This is my statement. It is not the Commission's statement, but it is my statement. But I know of no——

Representative VAN ZANDT. During the course of these hearings, this Project Sunshine has come up from time to time.

Dr. LIBBY. Yes.

Representative VAN ZANDT. Dr. Libby, just how did you arrive at naming this Project Sunshine.

Dr. LIBBY. Well, it happened in the summer of 1953 at the RAND Corp. conference at Santa Monica. I have been trying to think for the last several hours just how it happened. I do not remember, and I do not know, Mr. Van Zandt.

We recognized the need for some name, and one of the boys in the meeting invented this name, and we took it. I am sorry I have no better memory.

Senator HICKENLOOPER. Mr. Chairman, may I ask Dr. Libby—as I understand it, sunshine is stimulated by radiation, is it not?

Dr. LIBBY. Yes, sir; in the ultimate, sunshine is derived from radiation.

Senator HICKENLOOPER. And sunshine, as we know it, and as life exists, is completely vital to life?

Dr. LIBBY. Yes, sir.

Senator HICKENLOOPER. And the effect of the sun and radiation is vital to life. I am not trying to say how the term came up, but it seems to me there is quite a close correlation between sunshine and the effects on human life of radiation.

Dr. LIBBY. I am trying to find out how this name was invented. I am sorry I have not been more successful. I have given you the chronology of it.

Representative HOLIFIELD. There is this exception, however, that sunshine is beneficial to the growth of life, and radiation seems to be the other way. Is that not right?

Dr. LIBBY. At least radiation has many deleterious effects, Mr. Holifield. I think it has a few good ones.

Representative HOLIFIELD. As a Californian, I would like to say, the RAND Corp. being out of California, where we have a lot of sunshine, I would say, coming from California, this helps offset the reputation of smog we have out there.

Senator HICKENLOOPER. As long as we are in that field, Mr. Chairman, I might say, inasmuch as sunshine brings, and has over the millenniums, brought substantial amounts of radiation, perhaps it is that the more sunshine, the more danger there is to the skeletal structure of the human body. That might be argued in favor of those areas which are less blessed with sunshine. I do not know.

Representative COLE. Mr. Chairman, on this point of the name Project Sunshine, I fear a feeling may have developed that that name

was deliberately selected to mislead the public with respect to the importance of the subject under discussion.

Since you were connected to a rather direct degree with this project from its inception, can you assert unequivocally that the selection of the name "Sunshine" has no purpose or intent of misleading or minimizing the importance of the study?

Dr. LIBBY. Yes, Mr. Cole, I certainly can. It never had any purpose to mislead or be flippant about the whole matter. The name was selected—and I am afraid perhaps we did not pay too much attention to the name in selecting it. But there was never any intent to mislead or to minimize the importance of the hazards.

Senator ANDERSON. I thought you testified you did not know how it was selected. If you did not know how it was selected, how could you know the circumstances under which it was selected?

Dr. LIBBY. What I testified to, Senator Anderson, was I did not understand how the word "sunshine" rather than any other word was taken.

Senator ANDERSON. Then how could you answer Mr. Cole's question in the affirmative?

Dr. LIBBY. Well, we certainly did not select this word with any intent of misleading anyone about the seriousness of this subject. That is all.

Representative COLE. The witness may very properly testify he does not know how this was done, but he also may testify he does know why it was not done.

Senator ANDERSON. If you can prove a negative, you may go to it.

Dr. LIBBY. Fallout has been a subject of interest ever since the first atomic bomb was exploded. At the Alamagordo test, July 16, 1945, there were scientists present who were interested in fallout and studies were subsequently made of the sparse vegetation of that countryside.

The organization which is today known as the Health and Safety Laboratory came into being ith the establishment of the Commission on January 1, 1947. Scientists from the Health and Safety Laboratory made their first collection of fallout material on February 1, 1951, when radioactive snow was reported in Rochester, N. Y. At this time, assays of mixed fission products were made on snow and water from samples collected from throughout the Northeast. The source of this radioactivity as undoubtedly our very first Nevada tests conducted in the early spring of 1951—Operation Ranger. The first actual fallout collection network was established a few weeks later for Operation Greenhouse, an Eniwetok test series, and the collections were analyzed for mixed fission products; the network operated from April to June 1951, making collections in eight stations in the United States. The following year, 1952, the Weather Bureau and the AEC collected radioactive fallout at 120 Weather Bureau stations in connection with Operation Tumbler-Snapper.

Representative COLE. At that point, Mr. Chairman.

Dr. Libby, do you intend to indicate the present system of collection stations?

Dr. LIBBY. I would be very pleased to. It is not in my statement, though.

Representative COLE. Your statement says that in 1952 you did have these 120 stations. That was 5 years ago.

Dr. LIBBY. Right.

Representative COLE. I think the committee and the public would be interested to know what the present is.

Dr. LIBBY. I believe Mr. Eisenbud, who is in charge of this, did describe this system to you in earlier testimony, Mr. Cole. Did he not, Mr. Chairman?

I would be pleased to recount it.

He has a system now which is essentially worldwide, 2 sorts, I believe 3 sorts, really. He collects the gummed papers, which he described to you. He puts out buckets, or washtubs at various places to get a total collection. Then, in addition, we have a system of collecting soil samples on a worldwide basis. So we have a much more thorough coverage, not only of the United States, but of the whole of the Western World, at least, and through the U. N. Radiation Committee, I can say of the whole world to a certain degree than existed in this early time of 1952.

Representative COLE. Instead of 120 collecting stations located in the continental United States, can you indicate the approximate number of collecting stations throughout the world?

Dr. LIBBY. I would be hard put to give you even an approximate number. I am sure it is larger, but I can ask for that.

Representative COLE. Dr. Eisenbud is in the audience, and since this is a matter of general interest, let us have it in the record.

Dr. LIBBY. I am sorry. It comprises now only 94 stations in the United States. These are the gummed paper stations. We make a distinction between the gummed paper and the washtubs and the soil.

Ninety-four stations of gummed paper in the United States, with 75 now in foreign countries.

What I call the washtubs are located at seven stations in the United States, and in the following countries: Hawaii, Chile, French West Africa. Austria, Union of South Africa, Thailand, South Rhodesia, Pakistan, Kenya, Japan, Colombia, and Brazil. And this network is being extended.

Senator ANDERSON. Since we are considering the Hawaii statehood bill this morning, I think the Hawaiians would object to being put outside of the United States.

Dr. LIBBY. Well, we have had this network of gummed paper operating continuously since 1951 and 1952. The washtub or stainless steel pot system is just now beginning to operate. It was set out last fall, actually. And the soil collection data—well, I will describe those in my statement.

Representative VAN ZANDT. Dr. Libby, does this sampling go on around the clock, or just at a given time?

Dr. LIBBY. No, it goes around the clock, Mr. Van Zandt.

Representative VAN ZANDT. Around the clock?

Dr. LIBBY. Yes.

Representative VAN ZANDT. In other words, your gummed paper is in the open atmosphere around the clock, and picking up samples continuously?

Dr. LIBBY. Yes. The washtubs are, too. That is, you do not put the washtub out just when it starts to rain. You leave it out continuously. And after a rain you bring it in and swish it around to suspend the particulate matter and bring the rain and the sediment in for analysis. But you put the washtub right back out so that you get the total fallout in the area.

We have established rather definitely that the washtubs give good numbers that check with the total soil content of fallout. This has been done in 2 or 3 places quite carefully, and checks resulted.

Representative VAN ZANDT. Thank you.

Dr. LIBBY. Meanwhile, at the Oak Ridge National Laboratory, Dr. Nicholas M. Smith, starting in 1949, had made a theoretical analysis of the long-range aspects of fallout. Smith concluded that over a period of years strontium 90 would be the most hazardous component in fallout and that an accurate knowledge of the distribution of this substance over the world would be essential to any scientific estimate of the potential long-range health hazard due to fallout. In 1952, RAND Corp. was given a contract to make an independent study of fallout and this study culminated in the summer of 1953 in a conference of selected consultants who made an intensive overall review and evaluation of the fallout problem. The conference recommended that the study of mixed fission products, then current, be supplemented by a worldwide assay of the individual fission product, strontium 90, produced by nuclear detonations, and so Project Sunshine was born. Most of the information presented to you so far in these hearings, if we exclude genetics and the toxic effects of ionizing radiation, was developed in the Sunshine project.

Samples for assay have included soil, alfalfa, animals, dairy products, human bone, rain, well and spring water, snow, and many other similar materials from various parts of the United States and from countries all over the world. Some of the scientists were exceptionally eager to get started on the program and the first experiments had been performed before the 1953 conference adjourned. As a result, Sunshine was born with essentially three working laboratories—a group working at the Health and Safety Laboratory in New York City under the able direction of Merril Eisenbud and later Dr. John Harley; a group at Columbia University under the competent direction of Dr. Laurence Kulp of the Lamont Geological Observatory; and a group at the University of Chicago, which was initially under my direction and later under Dr. Edward Martell. A little later, Dr. Lyle Alexander, of the Department of Agriculture, became interested in Sunshine and has personally collected many of the extremely important soil samples which have been analyzed in the program. Subsequently, two commercial laboratories, Nuclear Science & Engineering Corp., in Pittsburgh, and Isotopes, Inc., in New York, were asked to assist in carrying the burden of isotopic analysis. In the last year or two, several other countries, notably the United Kingdom, have taken up the study, and the United Nations has organized, at the suggestion of the United States, the Scientific Committee on the Effects of Atomic Radiation with which all countries collaborate freely. Dr. Shields Warren, outstanding scientist and medical doctor, and the first director of our Division of Biology and Medicine, heads the United States delegation. This international committee has been very beneficial. The information furnished by the cooperating countries has been a substantial and significant addition to ours.

Originally, Project Sunshine was focused on the study of strontium 90 fallout and its effects, but with the passage of time, Sunshine has come to mean all of the Commission's activities directly connected with offsite fallout so that any summary of Sunshine activities must include the important work of Dr. Austin Brues and his collaborators

at the Argonne National Laboratory on the toxicity of strontium 90; of Dr. Cyril Comar at Oak Ridge on the metabolism of radiostrontium in humans and animals; Dr. William Neuman at the University of Rochester on the depoition of strontium 90 in bone; Dr. Kermit Larson, of the University of California at Los Angeles, on fallout materials in plants, and many others. At the present time, there are upwards of 50 contracts with outside laboratories bearing upon Sunshine and, in addition, work at the Commission laboratories.

Representative HOLIFIELD. Dr. Libby, this is a very impressive statement of the different projects which are engaged in in studying the effects of radiation. We asked Dr. Dunham for specific information in regard to numbers of people employed either directly or through contract. If that information is available, I believe this would be a good place to put it in.

Dr. LIBBY. All right, we will see that it is done, Mr. Chairman.

Representative VAN ZANDT. Mr. Chairman?

Representative HOLIFIELD. Mr. Van Zandt.

Representative VAN ZANDT. Dr. Libby, will you put in the record the 50 contracts, the names of the companies, as well as the amount of money involved, and the number of personnel employed?

Dr. LIBBY. We would be very pleased to do that.

Representative VAN ZANDT. And the nature of their studies?

Dr. LIBBY. Yes, sir.

Senator ANDERSON. Since there has been an interruption, maybe I can go back a bit.

You mentioned the work of the United Nations in organizating the Scientific Committee on the Effects of Atomic Radiation, and Dr. Shields Warren, whom we all recognize as a very fine person, heading the United States delegation. Is there a geneticist on the United States delegation?

Dr. LIBBY. The composition—I will have to ask Dr. Dunham to answer that.

Senator ANDERSON. I think we had some testimony from geneticists there was none.

Dr. DUNHAM. The official representative of the United States is Dr. Shields Warren. He has two alternates, Dr. Austin Brues, and Mr. Merril Eisenbud.

At the last meeting of the United Nations Scientific Committee, which was held in Geneva in April, he took with him as consultants, as did the representatives of the other member countries of this committee, two outstanding geneticists from this country—Dr. George B. Beadle of California Institute of Technology, and Dr. Sterling Emerson of the Division of Biology and Medicine.

Does that answer the question?

Senator ANDERSON. The answer to the question, then, would be, "No, there is no geneticist on the United States delegation." Is that not correct?

Dr. DUNHAM. That is absolutely correct.

Senator ANDERSON. It is a simple answer.

Dr. DUNHAM. There can be only one official delegate.

Representative COLE. How large is the official delegation?

Senator ANDERSON. And two people who accompanied him?

Dr. DUNHAM. Yes.

Senator ANDERSON. Who are these others that go along if they are not delegates?

Dr. DUNHAM. They are so-called alternates who may go along, and particularly act for the—officially act for the representative in his absence.

Representative COLE. Are either of the alternates specialists in any one field of biology?

Dr. DUNHAM. Dr. Austin Brues is a specialist in radiation pathology. He is an outstanding authority on the subject. Your committee asked him to testify as he did the other day.

Mr. Merril Eisenbud is not a biologist. He, however, is, as Dr. Libby has just indicated, the one who has been a prime figure in the development and accumulation of the information we have in this country on fallout. Therefore, it was felt appropriate that he be an alternate, because he lived this problem day in and day out.

Representative HOLIFIELD. Dr. Dunham, could you furnish now, early, for the benefit of the press and the audience, the numbers which we asked you for the other day? I think it would fit in at this point in the record.

There is a great deal of propaganda going around throughout the Nation that we are not concerned about this matter governmentwise, and I think this would help to show that there is concern on the part of the Congress and the Atomic Energy Commission, and that there is considerable effort both in terms of personnel and in money being devoted to a study of the problem.

Dr. DUNHAM. I have here a document I believe the committee already has copies of (p. 1393). I was planning to give it to you for tomorrow. I will read you the first page.

Scientfic man-years for sampling and analysis of radioactive fallout, including fission products, toxicity and transport, 253.

The effects of radiation on humans, mammals, and other organisms, exclusive of genetic studies, 449.

Treatment and methods of ameliorating radiation effects, 60.

Genetic effects of radiation, studies on human genetics, 12.

Experimental studies on the genetic effects of radiation on species other than man, 71.

Biochemical and microbiologic studies of radiation effects, 110.

Environmental studies, 4.

Dosimetry research, development of improved methods of measuring fallout, 47.

A total of 1,006 scientific man-years.

Representative HOLIFIELD. Thank you very much.

Do you have a complete presentation for tomorrow?

Dr. DUNHAM. It is already in the hands of the committee, I believe.

Representative COLE. You confused me by that last expression, "scientific man-years." Get it down to the number of people the Commission has engaged, either direct by contact, in the study of biological aspects of radiation hazards.

Dr. DUNHAM. The figure, if we gave you numbers of people, would be much larger, but it would also be misleading, because many people do not spend full time on this work.

Representative COLE. Give me the total number, and allow me to decide how far I have been misled.

Dr. DUNHAM. I do not have that number, but I will get it for you, Mr. Cole. I will be happy to get it.

Representative COLE. Would it be in the order of three or four thousand?

Dr. DUNHAM. It would be in that range, yes; I am sure.

Representative VAN ZANDT. Mr. Chairman?

Representative HOLIFIELD. Mr. Van Zandt.

Representative VAN ZANDT. Dr. Dunham, I asked a question the other day, but I think it should be repeated at this point in the record.

Are there any independent studies being made of the radiation hazards, that is, independent of Government, independent of the Atomic Energy Commission?

Dr. DUNHAM. If you are talking about the actual research work and the collection of data, I believe the Atomic Energy Commission is responsible and supporting by far the large majority of that work which is done in this country. If it is a matter of evaluation of the data, as you know, the National Academy of Sciences has a continuing group of committees reviewing this problem. They have been meeting ever since their report a year ago, and will continue to do so, and review the subject.

Representative VAN ZANDT. Dr. Dunham, I imagine that the AEC has access to the studies of the independent groups?

Dr. DUNHAM. That is right. We are kept in touch with each other.

Dr. LIBBY. But these groups are entirely independent, Mr. Van Zandt, in their functioning.

But on the point of geneticists, Senator Anderson, I assure you we have no intention of slighting in any way the subject of genetics. We consider it to be very important.

Senator ANDERSON. I assume you have heard about the testimony of Dr. Glass.

Dr. LIBBY. I have not read it; I am sorry, but I read the morning papers.

Senator ANDERSON. I am sure your agency does not differ from any other. You have them reporting to you what is going on.

Here is a group that met 22 times in the last 3 years while Dr. Glass has been a member of it. He had been hopeful, I guess, sometime that the Atomic Energy Commission would ask him what they thought about the project, but nobody thus far has.

Dr. LIBBY. You see the committee reports to Dr. Dunham, and I would like him to comment upon that.

Dr. DUNHAM. The committee reports through me to the Commission.

Representative COLE. What committee are you talking about?

Dr. DUNHAM. I assume Senator Anderson is talking about the Advisory Committee for Biology and Medicine.

Senator ANDERSON. Exactly, which is the one Dr. Glass testified about.

Dr. DUNHAM. That is correct. I think the record will show that on a number of occasions Commissioner Libby has specifically requested that this subject be on the agenda. It has been discussed at practically every one of the meetings in the last 2 years.

Senator ANDERSON. Were any members of the committee there?

Dr. DUNHAM. Members of——

Senator ANDERSON. Any members of the Advisory Committee there, or in absentia?

Dr. DUNHAM. This is the Advisory Committee meetings, I am talking about. At their meetings.

Senator ANDERSON. You were not trying to imply it had been brought up by Dr. Libby at the meetings of the Atomic Energy Commission?

Dr. DUNHAM. Oh, no. That is something else.

Senator ANDERSON. You allowed the Advisory Committee to talk about what it is supposed to advise about?

Dr. DUNHAM. That is right.

Senator ANDERSON. But do not let it get to the Atomic Energy Commission.

Dr. DUNHAM. I do not——

Senator ANDERSON. You say that Dr. Libby has asked this be put on the agenda. The agenda of what?

Dr. DUNHAM. The Advistory Committee.

Senator ANDERSON. The very purpose for which it is created.

Dr. DUNHAM. That is correct.

Senator ANDERSON. He asks that the subject for which it is created be put on its own agenda?

Dr. DUNHAM. Oh, no. He asks that they specifically consider the status of project Sunshine. He has done that on several occasions. So has Commissioner Murray.

Senator ANDERSON. How many times has the report of the Advisory Committee been an item on the agenda of the Atomic Energy Commission that you recall?

Dr. LIBBY. The Committee makes a report to the Commission every meeting, does it not?

Dr. DUNHAM. Yes. After each meeting they write a letter summarizing their deliberations and any recommendations they might have.

Senator ANDERSON. I guess you misunderstood my question. My question was: How many times has a report of the Advisory Committee been on the agenda of the Atomic Energy Commission?

Dr. LIBBY. I do not believe that the reports, as such, ever are on the agenda, Senator Anderson, but that does not mean we do not give them the most serious consideration.

For example, the General Advisory Committee's report is never, as such, on the agenda. Items which they report on and recommendations which they make will be on the agenda, but the Commission is reported to through the mechanism of a letter to the Chairman of the Commission, which is circulated to all members of the Commission. Just a technicality. It does not go on the agenda. We do pay attention to it. We certainly are most interested in supporting genetic research, and furthering its investigations in every way.

Representative COLE. Dr. Libby, a point of clarification. This Advisory Committee covers all aspects of the biological consequences of radiation, does it not?

Dr. LIBBY. All aspects of biology and medicine.

Representative COLE. Of which genetics is one element?

Dr. LIBBY. Yes.

Representative COLE. And I understand from Dr. Dunham's statement that you, as a Commissioner sitting in with this Advisory Com-

mittee, have from time to time specifically asked the Advisory Committee to give consideration to the genetic effects of radiation?

Dr. LIBBY. I cannot recall——

Senator ANDERSON. He did so testify.

Dr. LIBBY. I cannot recall specifically emphasizing the genetic rather than the somatic hazards, but we have repeatedly made it clear to the Committee that any words of advice or conclusions that they have on any aspect of the effects of radiation, whatever its origin be, be it weapons tests or accidents in peaceful uses—or whatever its origin—we certainly want the information.

Representative VAN ZANDT. Dr. Libby, let me ask you this question: In your opinion, as a commissioner, do you think that the subject of genetics has been adequately covered?

Dr. LIBBY. I am not a geneticist, and I know so little about the subject of genetics, Mr. Van Zandt, that I hate to answer that question. It seems to me that I do not know the answer. I know we do want to encourage good, capable research men to work in this field in every way we can, and I am sure Dr. Dunham can testify more definitely to your question. I would like to ask him to.

Dr. DUNHAM. I think I can best answer it, Mr. Van Zandt, by calling your attention to the fact that the Advisory Committee for Biology and Medicine as always had a geneticist on it. This indicates the preoccupation of the Commission with the genetics problem. The first Committee included Dr. George Beadle, of Cal-Tech. Following his 5-year stint, Dr. Kurt Sturn, of the University of California, took over, and currently it is Dr. Bentley Glass. Furthermore, since 1950, the Division of Biology and Medicine has always had a full-time geneticist of considerable statute on its staff, so as to be certain that this area would not be neglected.

Representative COLE. How large is the Advisory Committee?

Dr. DUNHAM. Seven people, I believe.

Representative COLE. And 1 out of the 7 has always been a geneticist?

Dr. DUNHAM. One has always been a geneticist.

Chairman DURHAM. That is just the Advisory Committee on Biology and Medicine?

Dr. DUNHAM. That is correct.

Chairman DURHAM. That does not include the Advisory Committee on the whole thing?

Dr. LIBBY. The law sets up the General Advisory Committee, and, because of the existence of the Advisory Committee on Biology and Medicine, there has been a tendency, I think, to not appoint biologists to the General Advisory Committee. So we have never had—I do not recall there ever has been a biologist or medical doctor on the General Advisory Committee. But it is for the reason that we have this special Committee for the area of biology and medicine.

Senator HICKENLOOPER. Mr. Chairman, may I verify this with Dr. Libby? As I understood the testimony of yesterday, first, the General Advisory Committee is an arm of the Commission; that is, it reports directly to the Commission?

Dr. LIBBY. Yes.

Senator HICKENLOOPER. And the Advisory Committee on Biology and Medicine is also an arm of the Commission and reports directly to the Commission. Is that right?

Dr. LIBBY. Well, it reports through the Director of Biology and Medicine, though I think the Committee certainly knows we are very glad to have them talk directly to the Commission at any time, and I try to attend the meetings when I can. I think your statement is correct, Senator Hickenlooper; yes. But there is a statutory connection which exists for the General Advisory Committee, which does not exist for the other Committee. You will not find the Advisory Committee on Biology and Medicine specifically mentioned in the Atomic Energy Act of 1954, I believe.

Dr. DUNHAM. May I amplify this?

Representative HOLIFIELD. Let's get to the main part of the testimony, now, and then we can have——

Senator HICKENLOOPER. If there is some amplification at this point, Mr. Chairman, I would like to hear from Dr. Dunham.

Representative HOLIFIELD. Go ahead, Doctor.

Dr. DUNHAM. I merely wanted to state that, when I said earlier the Committee reports through the Director of the Division, this is not actually in fact so. They report directly by letter, the letter that goes between the Chairman of the Committee and the Chairman of the Atomic Energy Commission.

Representative HOLIFIELD. And how does that differ from the General Advisory Committee? Do they report through the General Manager, or do they report by letter, or do they report directly to the Commission?

Dr. LIBBY. The Chairman of the General Advisory Committee reports by letter to the Chairman of the Commission.

Representative HOLIFIELD. Proceed.

Dr. LIBBY. At first it was believed that the work of Project Sunshine was so intimately concerned with weapons that it was necessarily secret, but it presently became apparent that more and more aspects were declassifiable; consequently, a year or so ago, virtually every aspect of the Sunshine project not already unclassified was declassified. It is also true, of course, that many of the problems which we think of today as part of Project Sunshine were not so considered in the beginning and had been in the unclassified areas since their inception. The information obtained has been issued publicly. With one exception, I do not know of any significant information on fallout in the possession of the Commission which is not available to the public.

Representative HOLIFIELD. Is that exception in the classified area?

Dr. LIBBY. Yes. That is in the next sentence. The exception is certain facts which would reveal information concerning intelligence and weapon design and, therefore, cannot be made public; however, your committee has access to these facts in executive session. The portion now classified is only a small segment of the large body of knowledge about worldwide fallout and, although important, is not vital in the understanding of fallout, its effects and its hazards.

There is another point I would like to make at this time about the study of worldwide fallout and that is that it is a scientific study. Thus it has as its objective just one thing, truth, the scientific truth. We have a consistent policy of encouraging all competent scientists, both here and abroad to contribute to the study. Many of these contributions can be comparatively indirect and can be carried out in most research laboratories as an adjunct to the regular work. In this con-

nection, I have frequently suggested particularly to those critics of the Commission's weapons testing program who are competent scientists that any contributions they might make in the way of scientific theories, data, or experiments would be most welcome.

Representative COLE. Mr. Chairman?

Representative HOLIFIELD. Mr. Cole.

Representative COLE. Would the chairman allow me to interrupt Dr. Libby again with reference to the studies of worldwide aspect of fallout?

Reverting to your system of sampling which you have indicated is substantially worldwide, as widely distributed as possible, do those studies support the assertions which have been made by some that the distribution of fallout is not widespread, is not general throughout the world, but rather is concentrated in the Northern Hemisphere?

Dr. LIBBY. Mr. Cole, the interpretation—I may say this: The only data that exists are the data Project Sunshine have collected and published. There are not any other data, except those few that have been collected in the last year or so by the other countries. So the majority of them are ours and whatever difference in interpretation there may be, or difference in statement, must be based on the same data.

Senator ANDERSON. I hope we talk about that, but I was going to wait for that portion of your statement, where you talked about the uniformity of stratospheric fallout.

Dr. LIBBY. Yes, sir; I would be very glad to discuss this question.

Representative COLE. All right.

Representative VAN ZANDT. Mr. Chairman?

Representative HOLIFIELD. Mr. Van Zandt.

Representative VAN ZANDT. Dr. Libby, this morning's Washington Post carried an article by Edwin Diamond, in which he refers to a scientific document entitled "Preliminary Data on the Effects of Atomic Bomb Explosions, and the Concentration of Radioactivity in Lower Atmosphere and Soil."

This is supposed to be a Russian document. Does the Commission have this document, or a copy of it in its possession?

Dr. LIBBY. Well, Mr. Van Zandt, I do not recognize it by the title, and I read every article that comes to the U. N. Radiation Committee from whatever source. That does not mean that I have not read it, and that we do not have it. I do not recognize the title.

I would say, from what Mr. Diamond said in the paper, that I have not read it. Maybe it is real new and we just have not seen it yet.

Representative VAN ZANDT. Thank you.

(A clarifying letter from Dr. Machta follows:)

JUNE 9, 1957.

To: For the record.
From: Chief, Special Projects Section, OMR, United States Weather Bureau.
Subject: U. S. S. R. fallout document.

Several questions by members of the Joint Committee on Atomic Energy at the fallout hearings dealt with a U. S. S. R. document entitled "Preliminary Data on the Effects of Atomic Bomb Explosions on the Concentration of Artificial Radioactivity in the Lower Atmosphere and in the Soil," edited by B. M. Isaev and D. L. Simonenko, Moscow, 1956, which was mentioned in an article by Mr. Diamond of INS in many newspapers last week.

Our office first showed this document to the reporter many weeks ago, as a result of inquiries about U. S. S. R. contributions to the International Geophysical Year in nuclear radiations. Mr. Diamond, however, neglected one fact in his

article, which the undersigned and Mr. R. J. List, of the United States Weather Bureau, gave him and repeated at least a half dozen times. This is the fact that at the recent meeting in Geneva of the United Nations Scientific Committee, the U. S. S. R. has withdrawn the data included in the report. In other words, there is no authentic fallout data from the U. S. S. R., insofar as we are aware. This is contrary to the facts of the newspaper article. My personal opinion is that the data in the report of the U. S. S. R. are wrong and withdrawal is justified.

LESTER MACHTA.

Dr. LIBBY. Our policy is to discover the truth about fallout and to make it public.

The Commission has provided its data to the United Nations Scientific Committee on the Effects of Atomic Radiation, which I mentioned a moment ago. Of course, the scientists employed by our contractors, and who are working in this field are encouraged to publish their findings in scientific journals—a practice which insures the availability of the information to all scientists everywhere. Any data or information which is not suitable for publication in scientific journals, but which has sufficient merit to warrant its distribution, can be and is published through the Technical Information Service Extension at Oak Ridge.

If one takes the summer conference at RAND in 1953 as the real beginning of the worldwide fallout study, then we began by considering all known aspects of the problem, and by planning a careful experimental attack on each of them. A continuous review has been going on ever since, conducted principally by the scientists engaged in the program, but vitally assisted by the study, The Biological Effects of Atomic Radiation, made last year by the National Academy of Sciences, and the continuing advice of the Advisory Committee on Biology and Medicine and the General Advisory Committee. Whenever it appears that some facet has been overlooked or is not receiving enough attention, an immediate effort is made to get the additional work going. This method of continuous criticism and evaluation has enabled the program to be productive and effective.

It is fortunate for our national interest—and for that matter the national interest of other countries as well—that this has been so, because were it not for the efforts of the scientists of Project Sunshine—they are relatively very few in number—not much would be known about worldwide fallout. As it is, the broad aspects of worldwide fallout are understood. In this connection, Dr. Dunham has asked that you put in the record 11 papers and technical speeches with detailed data. (See p. 16.)

As regards the physical rather than the biological facts about fallout, many possibilities still exist for minor controversy over detail, but no scientist who takes the trouble to learn what the facts really are will fail to agree with the overall picture. I know of no scientist who has studied the data who does not agree on the general amount of fallout received, the amount of strontium 90 in the body, the rainfall effect, and other features such as the stratospheric reservoir and the storage there for a time of many years. We still are not certain that 10 years is the best figure, but everyone agrees that it is a matter of years and the uniformity of stratospheric fallout is still under study as Dr. Machta has made clear.

Senator ANDERSON. Now that is the point where I would like to ask you a question, because you say the scientists do agree on the overall pictu. ɔ.

Dr. LIBBY. Yes.

Senator ANDERSON. Dr. Machta testified in here, and it seemed to me he testified that the stratospheric fallout was not uniform. I will just quote from him.

> After 2 years debris in the atmosphere from our Castle tests is still not uniformly distributed in the stratosphere. The upper air program of the Atomic Energy Commission can check this thesis in the near future.
>
> Delayed fallout has not been deposited uniformly over the earth. On the average, there is more delayed fallout in the north temperate latitude, even though the main injection was in the tropics, that is, the Marshall Islands.

Incidentally, this deposition of worldwide fallout was confirmed, I believe, by both Dr. Kulp and Mr. Eisenbud, who showed that the Northern Hemisphere had from 2 to 3 times as much strontium 90 as the Southern Hemisphere.

How do these check with your statement made on the 26th of April on uniformity?

Dr. LIBBY. I think they check very well. But let me explain that apparently paradoxical reply.

Senator ANDERSON. To a layman uniformity and nonuniformity are quite different terms, and you have used the term "uniformity" here again, and he keeps using the term "nonuniformity," Doctor. How do you put those into the same church?

Dr. LIBBY. I would like to use a chart for the rainfall in the Chicago area in the year 1955. I thought by selecting this one narrow thing I could explain it better.

Senator ANDERSON. It may be very helpful. But do you believe that strontium 90 is deposited uniformly over the world?

Dr. LIBBY. No, sir; and I never said that, sir. What I said was different—that the stratospheric components of the fallout might very well be uniform, and for the time being until we know better, we would so assume.

So the argument, really, if there be one—and I do believe it to be minor—is whether the stratospheric components of the fallout is uniform, Senator Anderson.

Senator ANDERSON. Do you think that sort of distinction occurred to the average person who is groping for information in this field?

Dr. LIBBY. I am afraid not, and I am sorry to have to agree with you, Senator. I think it is not. We have tried hard to explain the nature of the fallout from what we call the lower atmosphere, the troposphere. This stuff has no time to mix worldwide and comes down in the same general latitude as the bomb was fired.

The stuff that goes upstairs into the stratosphere stays so long that it has time to mix pretty much all over the world.

Now, the real point of discussion here, Senator, is this stratospheric material, which comes from large-yield megaton-class bombs—though it could come from small bombs if they were fired in the stratosphere—but the material that gets upstairs into the stratosphere and stays there for a matter of years. And Dr. Machta agrees with this.

Now the question is: How thoroughly does this mix before it comes down in its slow fashion?

This figure I have over here perhaps will help me explain it to you.

These are washtub data from the city of Chicago for the year 1955, where a washtub was placed on the roof of one of the buildings of the University of Chicago, and left out there continuously. It was only when it rained that we would empty the water and the solids that had accumulated and take those into the laboratory, and analyze them. The size of the dots indicates the error of the analysis.

I think you will notice at a glance that there is one big cliff in that curve of the strontium 90 fallout against time, which begins in January 1955, and extends throughout that year into January 1956.

There is a big cliff, and it is obviously correlated with the time at which we started firing small bombs in the Nevada test site, the so-called Teapot series.

So I say that of all of the fallout which occurred in the year 1955 in this particular area, on this particular roof, on the University of Chicago campus, most of it came from the Nevada series.

Now this is a difference of point of view which is not serious, in the sense that further information will straighten it out, and the difference for the prediction for the future is not measurable.

Dr. Machta and we agree about the occurrence of the stratospheric storage. We are not in disagreement. We have a range of opinion about the length of time it stays there.

The point about this band of stuff which lies in our latitude is that I say it is due to material that was deposited quickly, and I think Dr. Machta, to a certain extent, implies that part of that came from the stratospheric fallout which had not mixed.

Well, we do not know the answer to this.

I know that we have no place in the world where any rainfall at all occurs where we do not find fallout. I have measured snows from the South Pole, and every bit taken from the surface has detectable fallout.

We have had testimony from Dr. Kulp that bones from whatever part of the world, whatever part of the Southern Hemisphere, showed detectable strontium 90. The only places in the world where you do not find it are places where it has never rained.

Senator ANDERSON. I think we had one witness—and I will not try to recall his name—who testified that in the Latin American countries, or the Southern Hemisphere, it was half what it was in the Northern Hemisphere.

Dr. LIBBY. That is true.

Senator ANDERSON. Would that prove or disprove this theory of uniformity?

Dr. LIBBY. I think, Senator, that you and I understand; we must try to make this clear to everyone now.

You see that cliff there is not from the stratosphere, in my opinion. That cliff, that rapid rise in March, April, and May of 1955, was material that came from Nevada which had just come over. It did not go worldwide. That did not get in the Southern Hemisphere.

The flatter portion which you have there, in my opinion, was just about the same in the Southern Hemisphere. Now Dr. Machta says it was less. I do not think we know the answer, Senator.

Senator ANDERSON. I will read what you said on just the previous page. You said, "but no scientist who takes the trouble to learn what the facts really are will fail to agree with the overall picture."

Dr. LIBBY. I think that is right.

Senator ANDERSON. And you just got through saying you believe one thing and Dr. Machta something else.

Dr. LIBBY. No; he believes the same thing.

Senator ANDERSON. And naturally the rest of us get confused.

Representative PRICE. Will the gentleman yield?

Senator ANDERSON. Yes.

Representative PRICE. I think Dr. Machta said his findings—when questioned about your statement of April he said the disagreement came because of the fact that he was making his statement based on later findings.

Dr. LIBBY. I guess that is true, sir. I did not want to raise that point though. I mean it must be true; yes. That is, I am perfectly willing to change our mind if our stratospheric sampling—you see, we have a program now of going upstairs and actually finding out how much is there. This program is going and we will know this answer—and it is not very far away.

Representative HOLIFIELD. I think we are missing the point, if the Senator will yield. The point is not that there is a uniform distribution in the stratosphere. The point is, is the fallout from the stratosphere uniform or is it uneven, and I think Dr. Machta showed where the breaks in the stratosphere occurred and the downwinds came through those breaks that this was conducive to depositing the material unevenly on the earth's surface. Do you agree with that statement?

Dr. LIBBY. Certainly Dr. Machta is a most eminent meteorologist, and I am not a meteoroligist. I think your point is very well taken, Mr. Holifield, and may very well result that there is a band in both hemispheres, you see. That would follow from this analysis you have given us—that, if the mixing is at all uniform worldwide, there could be a band in both hemispheres.

Representative HOLIFIELD. It is also true, is it not, that the terrestial winds, the so-called jet winds, are more concentrated over the temperate zone, and as the material comes into a stream from other zones, why, it would tend to concentrate in the temperate zone; would it not?

Dr. LIBBY. Yes.

Representative HOLIFIELD. Your answer to that was "yes"?

Dr. LIBBY. Yes; I believe so.

Representative HOLIFIELD. On the chart over here, this really has very little, if anything, to do with stratospheric fallout. It is mostly the tropospheric fallout; is it not?

Dr. LIBBY. I think the stuff before and after the cliff is largely stratospheric.

Representative HOLIFIELD. You mean from January to March?

Dr. LIBBY. January to March, and then from——

Representative HOLIFIELD. That would be the stratospheric?

Dr. LIBBY. Yes. After the Teapot, Nev., series did you have a rise in the fallout, but that was tropospheric and not stratospheric. That was kiloton bombs.

Senator ANDERSON. Dr. Libby, in that speech in April you said:

For air-fired megaton weapons, our present indication is that the fallout is almost worldwide; and for reasons of simplicity, and in the absence of better information at the present time, we work on the model that this is a uniform distribution over the entire world of the material that falls from the stratosphere.

If you had to assume something, why not assume what the results show—that it was nonuniform distribution?

Dr. LIBBY. You see, sir, my interpretation of the results would be that they are not conclusive in showing nonuniformity.

Senator ANDERSON. No, but 50 percent of this radioactive material fallout of fission products goes into the stratosphere. Now it is quite significant if you start to assume all of this is going to come down evenly, but if you start to assume it may not come down evenly, there may be a band where deposits are heavy, it might affect people in the Northern Hemisphere, it might really concern them, and you might have to revise, it would seem to me, your estimate of the future fallout pattern in the United States.

I am only trying to say, why do you always say "uniformity," when the experience shows nonuniformity?

Dr. LIBBY. The experience does not show nonuniformity on the stratosphere, Senator, definitely.

Senator ANDERSON. I do not say that. You twisted it to mean something else. I said: "Why do we always have to assume uniformity in the fallout pattern of these materials, when all of the experience shows nonuniformity in fallout?" I am not talking about what is upstairs.

Dr. LIBBY. We certainly should not do that, and we have never done that, Senator; and I think it is important to make that clear.

Senator ANDERSON. You mean this speech does not assume that?

Dr. LIBBY. That speech is correct as far as I know.

Senator ANDERSON (reading):

We work on the model that this is a uniform distribution over the entire world.

Dr. LIBBY. Stratospheric, sir.

Representative COLE. Senator, read the rest of the statement.

Senator ANDERSON. I have read it with care.

Representative COLE. You will see it is not——

Senator ANDERSON (reading):

Further evidence and data on this are rapidly being collected which will undoubtedly settle the stratosphere horizontal mixing question.

That does not give me any more comfort than the first statement. You assume uniformity even here this morning. After Dr. Machta's very enlightening discussion, you start with the uniformity of stratospheric fallout. Why do you use the word "uniformity"? Why don't you use the word "nonuniformity"?

Dr. LIBBY. Because it is a question which is subject to some—like all scientific conclusions, you take the data and you draw conclusions from the data. The fact that banding of fallout occurs around our latitude, Senator, nobody argues about. Nobody argues about that. We do have this heavy banding in our latitude. And in my opinion it is due very largely to young fallout which never has been up there for years. It has been up there for weeks or months, and has not had time to mix. This difference of opinion is going to be settled. I do not believe that it is a major controversy. It is a minor one and will not seriously affect the general conclusions of this hearing.

Senator ANDERSON. It affects tremendously the question of how much fallout is safe, how much testing is safe, because if you assume that the pattern is uniform around the world, when actually it is 2 times or 3 times heavier in a given place, then you have, by this as-

sumption, lowered the possibility of damage from fallout. And the question is: Is that the reason why we say fallout is uniform over the whole world, whereas if we calculated it directly according to the way it is coming down, we might get a different answer?

Dr. LIBBY. You are certainly right, Senator.

Senator ANDERSON. That is my only point.

Representative HOLIFIELD. Dr. Libby, may I clear up one technical point here?

Dr. LIBBY. Yes.

Representative HOLIFIELD. The figure has been used in testimony before this committee of 50 percent of the fission products of a weapons test going into the stratosphere. Let us clear up now, if we can, that we cannot rely upon the 50 percent, and I ask you this question: Does it not depend upon the size of the weapon as to how much goes into the stratosphere? And therefore the percentage would vary from a large weapon, let us say, from as much as 75 percent going into the stratosphere and a smaller weapon that would puncture the stratosphere might deposit 25 percent, and a still smaller one would not go into the stratosphere at all? Is that clear? And if it is not, will you please clarify it?

Dr. LIBBY. It is quite true, Mr. Holifield, all that you have said. The statement about 50 percent is sort of rough. I mean there is nothing magic about that number.

Representative HOLIFIELD. No.

Representative COLE. On that point, if I may, Mr. Chairman; the size of the weapon is not the only factor which determines the amount of material that goes into the stratosphere, is it?

Dr. LIBBY. Oh, no, no.

Representative COLE. What are the other factors?

Dr. LIBBY. There are many factors. For example, if you took a kiloton bomb upstairs and fired it, it would be in the stratosphere.

Representative COLE. Well, the altitude has a great deal to do with it?

Dr. LIBBY. Surely.

Representative COLE. Does the nature of the weapon have anything to do with it?

Dr. LIBBY. The yield certainly determines whether it is going to push up the yield, among other things. That is, if you fire two bombs at the same distance above the earth's surface, the megaton bomb will get into the stratosphere and the kiloton bomb will not. Of course that is a rough general statement, too. I mean a 1-megaton bomb would not all go into the stratosphere, and some of the 100-kiloton bomb would go into the stratosphere.

Representative HOLIFIELD. And it is true, as you said, a thousand-ton bomb, if projected in the stratosphere by missile, would release all radioactive material in the stratosphere.

Dr. LIBBY. It would all be in the stratosphere.

Representative HOLIFIELD. In my evaluation I was, of course, talking about ground explosions.

Dr. LIBBY. Yes, I understood that, Mr. Holifield. But I thought it might be interesting to make this point that even kiloton bombs can give stratospheric fallout in the southern hemisphere if they are fired high enough in the air.

Senator ANDERSON. I was about to ask you how many people live in the stratosphere, but let me get down to this: Since the worldwide average is not calculable if it did fall down in a uniform pattern, would it now appear desirable or necessary to raise the predictions for the Northern Hemisphere, including the United States?

Dr. LIBBY. We certainly, in considering this tolerable limit should consider the fallout pattern, Senator, not a theoretical or simplified one. One should take this into account, those bumps, like that [indicating] which are due to Nevada. We have to add those things in there.

Yes. The answer to your question is, "Yes," one must take these into account. To reach an overall simplified figure, it might be justified to say, "If we fired everything in the stratosphere, this would be the figure." Or to take another one. If we fired everything in the troposphere, this would be the figure. But in the actual determination, you must take the actual figures for the fallout as distributed rather than depending on some theory. This is certainly true.

To proceed with my statement:

These essential points are generally agreed and the questions under debate are really largely political and sociological. For example, we agree that the extra radiation from the test fallout is a small fraction of the natural dosage we receive from our own bodies, our surroundings, the cosmic rays and a very small fraction of X-ray doses taken by many individuals.

Representative COLE. Mr. Chairman.

When you say, "We agree," who are you talking of?

Dr. LIBBY. I am thinking of the scientists who are studying the physical part of the Sunshine project; that is, the fallout, worldwide fallout.

Representative COLE. You are referring to the scientists who are directly engaged in the Sunshine project?

Dr. LIBBY. Yes, sir. Dr. Machta, and me, for example.

Senator ANDERSON. I had not intended to interrupt, but in the previous sentence you say, "the questions under debate are really largely political and sociological."

These 2 or 3 weeks have been set aside for the examination of witnesses who are primarily scientific in their approach. Are we wasting our time on scientific testimony, and not getting the political and sociological?

Dr. LIBBY. Oh, no. I think it is very important. The service that the Congress has done in holding these hearings is tremendous, and I commend you on it. You have gotten the facts out in a way that is just fabulous. It would have taken years to get this information out in the normal course, it seems. And it is so wonderful. No, sir, it has not been a waste of time.

Representative HOLIFIELD. At this point, Dr. Libby, because of the comment you made, you studied our agenda, which was prepared with a great deal of care and with a great deal of scientific advice by our staff members and scientific consultants, and you have been to some of these hearings. Do you consider that these hearings are being held in a fair and impartial manner, and in a beneficial manner to the people?

Dr. LIBBY. I certainly do, Mr. Holifield. You could not have done a better job, in my opinion. It is possible you might have taken up

some other subjects, but I would not have been able to devise a better program or set of hearings than you have conducted. I certainly commend you for it. No criticism at all.

Representative HOLIFIELD. We asked for suggestions, as you know, from the AEC.

Dr. LIBBY. Yes.

Representative HOLIFIELD. On the preparation of the agenda. And of course, we have tried to limit it as much as possible to scientific testimony.

Dr. LIBBY. Yes.

Representative HOLIFIELD. Now we recognize that there are other fields, sociological, political, and moral fields, of interpreting the effects and the reasons for having these tests; but it is not the purpose of the committee to get into that in these hearings. We are trying to collate a great amount of scientific information, so that people can make their decisions on information and statistical data from reputable sources, rather than upon uninformed statements.

Dr. LIBBY. Yes. I certainly commend you for it.

Senator HICKENLOOPER. Mr. Chairman?

Representative HOLIFIELD. Senator Hickenlooper.

Senator HICKENLOOPER. May I ask Dr. Libby about my interpretation of his statement, which, of course, came to my attention when he read it, that—

> These essential points are generally agreed and the questions under debate are really largely political and sociological.

I interpret that to mean not that there were not scientific data involved here at all, but that the public has been debating the sociological and political implications of this, and that is one of the great interests in the minds of the public which might be clarified, or some scientific truth be developed.

Dr. LIBBY. Yes.

Senator HICKENLOOPER. Which would dispel a great many fears and doubts, and all of those things that have been created by hysterical journalism on occasion, and headlines which seek, or which do, in effect, create fears and minimize the actual facts. I took that to be your reference.

Dr. LIBBY. That is the sense of it.

Senator HICKENLOOPER. I do not mean to have you pass on the question of distorted understandings of these things, necessarily, but there is a social and political concern in the country about these things which scientific facts may give many answers to.

Dr. LIBBY. That is right.

Senator HICKENLOOPER. I will frankly say I have seen many news stories which attract the avid interest of the people, and I have had telegrams on them about the terrible effects of these tests, which in my opinion are not borne out by the facts in these hearings, but still they get into the social and political thinking of people as a result of what at least to me is a misunderstanding of the actual facts and data that are brought out in these hearings.

Representative HOLIFIELD. Referring again to your sentence—

> These essential points are generally agreed and the questions under debate are really largely political and sociological.

would you not also modify that statement to include a difference of interpretation of the meaning of certain scientific facts?

Dr. LIBBY. Yes, I certainly would.

Representative HOLIFIELD. As well as political and sociological?

Dr. LIBBY. Yes.

Representative HOLIFIELD. There is an honest difference of opinion among scientists as to what the facts which they are agreed upon mean, how they should be interpreted in relation to the effect upon human beings; is there not?

Dr. LIBBY. There certainly is, particularly in the biological side, and particularly—well, particularly in the effects of fallout on the human body. There is not such a range of disagreement about the amount of fallout, or how much is where or how much has been there. There is not so much disagreement about these.

Representative HOLIFIELD. Particularly in the field of genetics.

Dr. LIBBY. That is my impression, Mr. Holifield.

Representative HOLIFIELD. There seems to be a very great deal of unanimity in the opinion of geneticists that people in the area of science in which they are most interested are more deleteriously affected than in the biological, physiological sense.

Dr. LIBBY. I have been reading the testimony yesterday with great interest. As I say, I am not a geneticist in any way, but it certainly is interesting to hear what the gentleman had to say. My impression agrees with yours.

Representative HOLIFIELD. You may proceed.

Dr. LIBBY. We agree that the radiation given new bone—as in children—from strontium 90 amounts now from 1 to 2 percent of the natural dose and that the increase in dose from a wide variety of ordinary experiences such as living in the mountains, moving from one locality to another where the difference in uranium and thorium content of the ground may be very different, living in a brick instead of a wooden house—all these normal experiences give doses which far exceed those from fallout. This we all agree is so.

Senator ANDERSON. Dr. Libby, right there. Do we also not then worry about what this maximum permissible dose is going to be when some of this fallout descends from the stratosphere?

Dr. LIBBY. No, sir, not at all. But I am showing here the wide range of general agreement on the physical aspects of the fallout problem. Everybody agrees that the fallout dosage is very small compared to both the natural dosage and the variation in the natural dosage.

Senator ANDERSON. Dr. Kulp, in his testimony, indicated that if we proceed at the same rate of testing, in 30 to 50 years we would get up to 25 to 50 percent of the maximum permissible dosage.

Dr. LIBBY. I am talking about the present time, Senator. The present time. You see, when you get into the future, you get into theory.

Senator ANDERSON. It is like erosion in my State. If you go out and look at a field, you will say, "We do not have to worry about runoff at the present time. It is not doing anything but dipping a little bit." And then it dips a little bit more, and finally you have a gully. We are interested in what happens 50 years from now.

Dr. LIBBY. Absolutely, we certainly are.

Senator ANDERSON. That is the reason why we might recognize this. What do we do with the acceleration of tests? If we have new countries coming in with tests, and the tests pick up, we raise this figure of 1 to 2 percent very decidedly, do we not?

Dr. LIBBY. Where is the wide difference of opinion? Why do some say testing should be continued despite the fallout hazard which they regard as tolerable considering the advantages continuance of testing has, and others say essentially the opposite? The differences in opinion about the scientific facts are not the real issue. The differences exists, but they do not explain the wide divergence in final conclusions.

Representative HOLIFIELD. There was a challenge put out, Dr. Libby, in this hearing that the Commission should come forward with a clear-cut statement regarding the scientific reasons for the continuance of testing. The geneticists gave reasons which they thought should be considered in the elimination of testing.

Now we are facing, for instance, in Nevada, a series of tests. Do you intend in your statement, or could you at this time give some of the scientific reasons—I am not talking about moral or philosophic reasons—but some of the scientific reasons why we consider, if we do, that testing should be continued?

You might divide that up into two sections, into the military area and also into the area of increasing our knowledge from a protective standpoint.

Dr. LIBBY. I would like to ask you, Mr. Chairman, for permission to prepare a statement on this point for the record, because I think what I would say off the cuff, so to speak, would be less helpful than something I could say after careful consideration. I would be very pleased to do that.

Representative HOLIFIELD. This is the thing I think we ought to be alert to—an affirmative drive for the acceptance of democratic ideas, instead of always being on the defensive side in relation to Russian propaganda in tests.

I think if you will prepare a careful statement, we will have it appended to your presented statement today, so that we may have this subject covered also (see p. 1373).

Dr. LIBBY. I certainly will, Mr. Chairman.

Representative COLE. Mr. Chairman, on that point.

Representative HOLIFIELD. Mr. Cole.

Representative COLE. I am advised that this morning in the press conference at the White House, the President discussed the question of the need for continuing the weapons testing, the subject of the hazards of radioactive fallout; and I would like to ask at the conclusion of the meeting this morning, a synopsis of that press conference be inserted in the record.

Representative HOLIFIELD. The committee will consider accepting that for the record. Up to now we have received testimony from scientists. I do not consider the President of the United States a scientist. He may have the advice of scientists, but unless the committee directs the chairman to break our rules of presenting evidence from nonscientists, we will have to take specific action on that request in executive session.

Representative COLE. Do I construe the chairman's statement, then, as being an objection to my request that the President's press conference be inserted in the record following Dr. Libby's testimony?

Representative HOLIFIELD. It is not an objection; it is a matter of postponement for the committee to decide upon, as we have already agreed we will have no one but scientists to testify during this set of hearings. And we have turned down many people of outstanding character and belief throughout the Nation because of the fact they were not scientists because we want to hold this to a collection of scientific testimony.

Representative COLE. Mr. Chairman, I am going to at this time ask unanimous consent that the President's statement at the press conference this morning on this subject be inserted in the record at the point following Dr. Libby's testimony this morning.

Senator ANDERSON. I would hope that might be done, because the scientists are going to get a supplementary statement, and it may be well to have the official position of the Government on this. I think this might be all right, Mr. Chairman.

Representative HOLIFIELD, There is a unanimous consent request before the committee. If it is the will of the committee, the chairman will entertain the motion of Mr. Cole.

Those in favor of Mr. Cole's motion signify by saying "Aye."

Those against say "No."

(Representative Holifield was the only one voting no.)

Representative HOLIFIELD. Proceed.

Representative COLE. What was the conclusion?

Representative HOLIFIELD. The conclusion of the vote is a vote of 4 to 1 in favor of inserting it in the record. It will be inserted.

The Chair may ask to have other nonscientific statements put into the record at a later date, and if that request is made, we hope that the committee will also agree to the same principle.

Proceed, Dr. Libby.

Representative COLE. Well, Mr. Chairman, I do not want to belabor this point, but to make certain the extent to which the action we have just taken creates a precedent. It has been my understanding that in order for material to be inserted in the hearings requires a unanimous approval of the committee.

Representative HOLIFIELD. There has been no such action on that point by the committee.

Representative COLE. I know. Therefore, my request was a unanimous consent request. If there is a single objection, my request will not be accepted.

Senator ANDERSON. Let me plead with Mr. Cole not to worry about that. I think when we get to considering it we may come to the conclusion that these scientists are asked for an explanation of America's point of view, it is proper for the President of the United States to outline what the point of view is. I think we can solve it without any difficulty. I think we would like to insert it in the record, and I certainly would favor and not oppose it. I do not believe it is a precedent.

Representative HOLIFIELD. I have no personal feeling about the matter. I am merely trying to conform to the rules which were decided upon in executive session, and my vote is still "no" until the rules are changed.

Proceed, Dr. Libby.

Dr. LIBBY. Testing constitutes a small risk—very small compared to ordinary risks which can be tolerated. It is not contended that there is no risk. But all life, and every minute of our day and night, is

measured in terms of risk—40,000 highway deaths each year in this country, accidents in the home, et cetera. We make our choice: How much risk are we willing to take as payment for our pleasures—swimming at the seashore, for example—our comfort, or our material progress? Here our choice seems much clearer. Are we willing to take this very small and rigidly controlled risk, or would we prefer to run the risk of annihilation which might result if we surrendered the weapons which are so essential to our freedom and our actual survival?

Senator ANDERSON. Right there, Dr. Libby, we have much to talk about, I would think. In your words: "Are we willing to take this very small risk?"

Do you regard this a very small risk?

I am referring to the fact that Dr. Russell, who is the principal geneticist at Oak Ridge National Laboratory, was quoted in a Science Service news story as saying that:

> Offspring from a man exposed to such radiation will have their lives shortened on the average of 20 days for each unit of the radiation their father had received.

We figured that out to about 22 years when we attain this maximum period. Then Dr. Russell revised his figures to mean from 5 to 35 days, and at the lowest it would come to about 11 years.

Would you think the shortening of life in offspring to the amount of 11 years was a very small risk?

Dr. LIBBY. Did I understand you to say that the present fallout would shorten our lives 11 years?

Senator ANDERSON. No, you did not.

Dr. LIBBY. I am sorry, sir.

Senator ANDERSON. I quoted Dr. Russell. I thought it would be better if I stayed with the scientists, and I quoted Dr. Russell, who is the principal geneticist at the Oak Ridge National Laboratory, who should be well known to you.

Dr. LIBBY. Yes, sir.

Senator ANDERSON. I referred to a story put out by Science Service which Dr. Russell explained. I think it has to be taken in view of his explanation. I was very happy we had it, because it was most helpful.

The story said: "Offspring from man exposed to such radiation"—and his radiation was neutron radiation from an atomic bomb. I had better read the first paragraph, Dr. Libby.

Dr. LIBBY. I do not know of this.

Senator ANDERSON. I recognize that, and I am sorry. I will be happy to send you the clipping.

> Neutron radiation from atomic bombs can shorten the life of a man's children, Dr. W. L. Russell, the principal geneticist at the Oak Ridge National Laboratory here has found. Offspring from a man exposed to such radiation will have their lives shortened on the average of 20 days for each unit of radiation their father has received.

I do not know how much radiation he is going to have from an atomic bomb. I do not know how much he is going to have from atomic testing. I am not concerned about that, to try to measure it. But here is a scientist—and I am happy to have your assurance that all scientists are pretty well agreed on these essential facts—who believes it will shorten life. And when we discussed it the other day—I hope I do not misquote Dr. Russell; I do not mean to—he ex-

plained the 20 days, and said perhaps a 5 to 35-day figure might be a much better figure.

But do you regard that shortening of life in succeeding generations as a very small risk?

Senator HICKENLOOPER. Mr. Chairman, would the Senator yield to the Senator for a question before he answers the question?

Senator ANDERSON. I recall the old radio show where the Baron said, "The Baron always asks the questions," but I will yield.

Senator HICKENLOOPER. I understand, but I would like to have the Baron answer the full question.

It was my understanding of this testimony it was qualified by saying that a man who got the maximum dose would suffer, and the testimony seems to be replete with the fact that we are in no danger at the present time of coming anywhere near the maximum dose.

Senator ANDERSON. I will be happy to read it. I read then, and I will read now from the news story which does not talk about maximum doses, and says, "Neutron radiation from atomic bombs."

The question then came, If a man should get a maximum dose of, say, 400 roentgens, it would shorten life 10 or 20 years. But I tried to avoid that by pointing out he said it can shorten the life of a man's children.

If Dr. Libby questions that, then we can have Dr. Russell to defend himself at a later time.

Do you believe that neutron radiation from atomic bombs can shorten the life of a man's children?

Dr. LIBBY. I have nothing but respect for Dr. Russell. I do not know the details of his study. This is outside my field.

I would point out to the Senator, though, that there are no neutrons in fallout radiation. I am not saying this to beg the question. I do not know whether Dr. Russell has studied the effects of fallout radiation but neutrons are emitted only instantaneously when the bomb is fired, so you do not get neutrons from fallout.

Senator ANDERSON. Do I understand Dr. Russell was on the Sunshine Project?

Dr. LIBBY. Surely, but I hesitate to comment on Dr. Russell's statement, since I have not seen it, Senator.

Senator ANDERSON. Very well.

Dr. LIBBY. I will be very pleased to answer your question for the record after reading the statement.

Senator ANDERSON. I will skip the words "very small," and come to the next. "Are we willing to take this very rigidly controlled risk."

Dr. LIBBY. Yes.

Senator ANDERSON. How rigidly is this controlled? Do we have any control over Russia as of now?

Dr. LIBBY. Well, I was speaking more about our rigid controls, which are very rigid.

Senator ANDERSON. But we are not the only people that are depositing fission products in the atmosphere, are we, Doctor? Are we?

Dr. LIBBY. We certainly are not.

Senator ANDERSON. All right. If we are not, do we have any control over what Russia does?

Dr. LIBBY. Obviously no.

Senator ANDERSON. Do we have any control over the British?

Dr. LIBBY. Obviously no.

Senator ANDERSON. And there may be a fifth or a sixth or a seventh country coming along. Do we anticipate we will have any control over them?

Dr. LIBBY. I would not comment about them, because I would not know. But the point is this, Senator: We do have control over ourselves, and the debate is whether we stop testing, is it not?

Senator ANDERSON. No, I do not think so, at all.

Dr. LIBBY. Well, part of it.

Senator ANDERSON. I think the debate is whether or not the world tries to bring this under some sort of control.

Dr. LIBBY. Which we are all for.

Senator ANDERSON. I was particularly attracted, if you do not mind my saying so, to the testimony given by Dr. Langham, in which he suggested a level of 10,000 megatons of fission products put into the atmosphere as a possible goal toward which all countries——

Dr. LIBBY. You do not mean 10,000 megatons.

Senator ANDERSON. Ten megatons. Did I not say 10 megatons of fission products? I am sorry. I meant 10 megatons yield equivalent of fission products put in the atmosphere. We have been putting it into the atmosphere at about the rate of 10 megatons a year, and he thinks that is about the maximum, and certain other scientists agree with him, and some of us are interested in trying to bring this situation worldwide under control.

Now, the language of your statement says: "this very small and rigidly controlled risk." And I question the term "rigidly controlled risk," because I realize it is like the term "clean bomb," it makes good reading. But it is not rigidly controlled, is it?

Dr. LIBBY. I had reference to our controls, sir, and they are rigid.

Senator ANDERSON. Well, I go on—"or would we prefer to run the risk of annihilation which might result if we surrendered the weapons which are so essential to our freedom and our actual survival."

Is that a suggestion that if we had control we would have to disarm?

Dr. LIBBY. It is my opinion, Senator, that this testing is an integral part of armament and cessation of testing is a part of disarmament. I think most people agree with that.

Senator ANDERSON. You say you want testing continued?

Dr. LIBBY. I say, and what I did say, Senator, was that testing was an integral part of armament, and so stopping testing is a disarmament move, and I think most people agree with that.

Senator ANDERSON. And I understand you favor continuing testing?

Dr. LIBBY. I am in favor of disarmament under proper controls, very strongly, sir.

Senator ANDERSON. I again come back to your letter to Dr. Schweitzer, in which you say:

> Of course, a workable, safeguarded system of international disarmament is a paramount objective of the United States Government, and one which we must work for and hope and pray will be achieved.

Dr. LIBBY. Yes.

Senator ANDERSON. If you are going to work for it, and hope and pray it would be achieved, an initial step certainly would be to stop testing, a step to disarmament?

Dr. LIBBY. The cessation of testing would be a disarmament move.

Senator ANDERSON. And you are in favor of disarmament?

Dr. LIBBY. In general, yes; under proper controls.

Senator ANDERSON. Very well.

Senator HICKENLOOPER. Mr. Chairman?

Representative HOLIFIELD. Senator Hickenlooper.

Senator HICKENLOOPER. May I ask, Dr. Libby, I take it that what you are saying is that you do not believe it is in any interest of our own future security if we stop testing alone and permit Russia to go on testing, and other nations in the world to go on testing. Is that correct?

Dr. LIBBY. That is exactly correct, Senator.

Senator HICKENLOOPER. And you are thoroughly and completely in agreement with the disarmament which would include the stopping of testing if reliable controls were had, and reliable assurances by other nations that their testing would also be stopped, and the field of weapon experimentation would be eliminated?

Dr. LIBBY. That is right, sir.

Senator HICKENLOOPER. I just wanted to get that straight here.

Representative HOLIFIELD. Proceed, Dr. Libby.

Dr. LIBBY. The cause for real concern is not the deleterious effect of radiation resulting from weapons tests, but rather what would be the effect of the infinitely greater amount of radiation which would result from the massive use of nuclear weapons in warfare. Here we would be dealing with excessive radiation, not to all the people of the world as has been suggested, but quite probably to large numbers of people residing in areas of substantial contamination.

Senator ANDERSON. Right there, Doctor, did the geneticists not seem to indicate yesterday that radiation spread around the world? What about these areas of substantial contamination, Doctor? This is just narrowed down to a city or township near where it happened.

Dr. LIBBY. I would again have to study their statement, and I am not a geneticist. It would seem to me there is no doubt there would be damage to very large numbers of people. Whether there may be remote corners of the world which would escape is a question I think we do not know the answer to, really.

With regard to the people so overexposed——

Chairman DURHAM. Dr. Libby, yesterday Dr. Glass, I believe, testified that in some 2,000 skeletons strontium 90 showed up in all of those in all parts of the world.

Dr. LIBBY. Yes.

Chairman DURHAM. I mean, you do not doubt the fact that it falls out in some quantity around the world, do you?

Dr. LIBBY. No, sir. The question is what the fatalities would be in terms of an atomic war, nuclear war.

Chairman DURHAM. That is why I asked the question, because you are speaking to numbers here now, of course, in at least an act of war.

Dr. LIBBY. Right.

Chairman DURHAM. In your statement, "quite probably to large numbers of people residing in areas of substantial contamination"—what do you mean by large numbers?

Dr. LIBBY. Well, Mr. Durham, what I wanted to bring out is what we call the cigars, that is, the areas of local fallout, which Mr. Holifield spent so much time working on in connection with civilian defense. We have been in these hearings talking about the other side of the coin, the worldwide fallout. In the local fallout pattern which you get that

looks like a cigar, perhaps 7,000 square miles in area as from the March 1954 detonation, and so on.

We must not forget those things. On the one hand we have the subject of this hearing, which is worldwide fallout, and on the other hand we have the blanketing of the country with local fallout pattern. This is the distinction I had reference to.

There is absolutely no doubt that the people in those areas of heavy local fallout would be seriously damaged unless they took care of themselves, and looked to the problem ahead of them. There is absolutely no doubt.

Now the question of worldwide fallout and how serious it will be from the genetic point Senator Anderson brought out, well, I do not think we know; and I think the geneticists would be the first to agree they are not absolutely certain in the magnitude of effect. We know the effects are not good.

Chairman DURHAM. You know the life of strontium 90, though?

Dr. LIBBY. Yes, sir.

Chairman DURHAM. You know, of course, the first contamination is not the end of it.

Dr. LIBBY. Oh, no. There is no doubt there will be serious effects every place in the world if there were a nuclear war.

Representative HOLIFIELD. Proceed.

Dr. LIBBY. With regard to the people so overexposed there would be serious increases in the pathological effect of excess radiation, such as cancer and leukemia. There would also be the genetic effect which would manifest itself in the children and the children's children of such people.

Let us consider the present situation. We can take our normal experience with natural radiation as strictly limiting possible effects from the fallout—since natural radiation is so much larger. It is a queer fact of the present situation that we know far more about fallout dosage than about natural dosage.

The Sunshine project is only beginning measurements on natural radiation, though, as you have seen, its amassed data and its understanding of fallout makes it one of the most impressive scientific investigations ever made. Somehow, even those who have known for years about the wide variation in natural dosages have been more concerned with the study of test fallout than of building materials, homes, public buildings, schoolrooms, et cetera.

(Remarks prepared by Dr. Willard F. Libby, Commissioner, United States Atomic Energy Commission, follow:)

NATURAL OCCURRENCE OF RADIOACTIVITIES AND RADIATION

The radiation dosages that people receive from natural radioactivities and cosmic rays are of importance, for it is only from these dosages that limits on the deleterious effects of radiations received over long periods of time at low rates as in the case of radioactive fallout can be obtained. Studies of vital statistics for populations exposed to varying natural dosage levels offer hope for determination of human susceptibility to radiation effects both somatic and genetic. A brief summary report on this, published some time ago, is offered for the record. It was prepared with the thought of application to the fallout studies in mind: Dosages from Natural Radioactivity and Cosmic Rays, W. F. Libby, Science, 122, 57–58 (1955). (See p. 1459.)

Other lengthier and more complete studies are listed:

1. P. R. J. Burch and F. W. Spiers, Science 120, 719 (1954).
2. P. R. J. Burch, Proc. Phys. Soc. Lond. A67, 421 (1954).

3. Bengt Hultqvist, Kungl. Svenska Vetenskapsakademiens Handlinger. Fjarde Serien. 6, No. 3 (1956).
4. Radiological Data in Japan, Government of Japan, Yoshio Hiyama. U. S. Scientific Committee on the Effects of Atomic Radiation, A/C.82/G/R.70, March 27, 1957.
5. The Toxicity of Skeletal Irradiation at Naturally Occurring Radiation Levels, Robert A. Dudley, April 1, 1957.

I would call attention particularly to the work of Hultqvist on building materials in Sweden, particularly brick and light weight concrete containing alum shale. Measurements in this country indicate that our bricks may not differ appreciably.

Natural dosage in middle of rooms in Swedish homes (mr/yr) (Hultqvist)

Wood	83± 9
Brick	143±22
Concrete (light weight with alum shale)	215±65

We are beginning a survey on natural radiation dosages which should elucidate this and many other points. In the initial results we find that very appreciable variations from spot to spot occur just as would be expected on the basis of the occurrence of thorium, uranium, and potassium in various minerals. Inside a granite church in New York State the dosage was double that outside in the same vicinity.

The close reader of the reports cited above will note a discrepancy in the magnitude of the cosmic ray dosages reported. This has its ultimate origin in a real discrepancy in the physical measurements as between Professors Millikan and Neher in California and Dr. J. Clay and his school in the Netherlands. I have chosen the Millikan-Neher result which seems to have been confirmed in the Japanese report submitted to the U. N. Committee a few weeks ago, whereas others have selected the Clay measurements which give dosages about 70 percent of those of Millikan-Neher. The altitude variations are the same in all studies within the error of measurement.

We have only recently started measuring brick and arranging for widespread natural dosage studies, and most of what we know has come from studies abroad, part of which were through the United Nations Committee mentioned earlier.

For example, in Sweden, Hultqvist has shown that homes of wood give an average dose in the center of their rooms of 80 to 90 milliroentgens per year, while those of brick give 140, and those of lightweight concrete with alum shale, over 200. These numbers are to be compared with present United States fallout doses—and remember that the United States—I know there is an article in the morning paper that said something different—as far as we know is the highest in the world. The present United States dosage is 1 to 5 milliroentgen per year.

Certain areas of India occupied by many thousands of people have natural dose rates—due to the thorium in the sand—several times our average of about 150 milliroentgens per year. An important article on natural dosage appeared in one of our own technical magazines a few days ago. Written by Prof. H. V. Neher, a colleague of Robert A. Millikan's, it presents important early data gathered prior to any nuclear weapons tests. I would like to refer to the principal graph from Professor Neher's paper. It is upon the stand over there.

(The article including the graph referred to follows:)

[Reprinted from Science, v. 125, May 31, 1957, pp. 1088–1089]

Gamma Rays From Local Radioactive Sources

There is considerable interest at the present time concerning the possible effects of manmade radiations on man himself. Because one source of these radiations is of worldwide extent, the interest has also become worldwide. Although considerable literature now exists on the subject of manmade radioactive contamination, on the one hand, and on the biological effects of radiation, on the other, the actual importance of the first as far as the second is concerned has often been obscure. It is thought desirable at this time to present some independent experimental data that will allow individuals to reach their own conclusions.

As early as 1928, R. A. Millikan became interested in the gamma rays emitted by local radioactive materials in the soil and rock at various localities in order to determine the effect of these radiations on the cosmic-ray measurements in which he was primarily interested. These measurements extended from California into the Rocky Mountain area and on up to Churchill, Manitoba.[1] They probably represent a unique series of measurements, since they were made before manmade contamination became widespread.

Anionization chamber measures directly the quantity of interests as far as the biological effects of gamma rays are concerned, and this is the instrument here employed. One of the instruments Millikan made and calibrated is still in good condition after 26 years and is very convenient to use. A recent redetermination of the absolute value of the calibration[2] agrees with Millikan's value to 0.3 percent. In this survey, Millikan's instrument has been used for some of the measurements, and a more modern ionization chamber[3] for others. The two give essentially the same answer. Both were used unshielded in the measurements reported here.

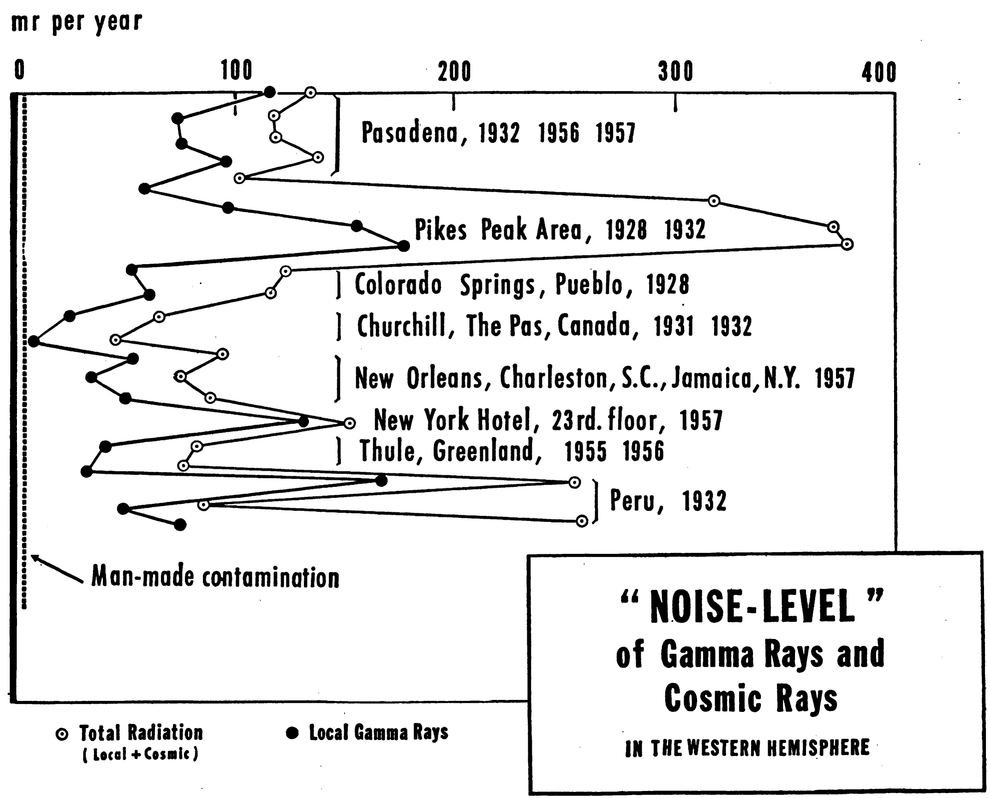

FIGURE 1.—"Noise level" of gamma rays and cosmic rays in the Western Hemisphere, Abscissas roughly increase with increase of distance from Pasadena. The amount of manmade contamination is taken from the National Academy of Sciences report, Biological Effects of Atomic Radiation (see footnote 7). As is stated in that report, "* * * United States residents have, on the average, been receiving from fallout over the past 5 years a dose which, if weapons testing were continued at the same rate, is estimated to produce a total 30-year dose of about 0.1 roentgen" (an average of 3 mr. per year).

In figure 1, most of the values taken during the years have been entered. The ordinates are in milliroentgens (mr.) per year. To convert into ion pairs per cubic centimeter, per second in 1 atmosphere of air, divide the ordinate by 15. The various stations are plotted as absciees with the same increment from one to the other. Roughly, the stations get farther from Pasadena with increase in abscience. The chief reason for plotting in this manner was to bring out the variability of radioactivity from one station and region to another.

Measurements were made of the total radiation at a given station; then the known contribution from cosmic rays[4] was subtracted to get the effect of the gamma rays from local radiation only.

In the Rocky Mountain region, the local radiation is high, presumably because of the granite, which is known to contain something like 4 g. of uranium and 15 g. of thorium per ton.[5] In Peru, the radioactivity of the coastal plain is much the same as that of the Mississippi region near New Orleans. The local radiation at an elevation of 15,000 feet in southern Peru is only slightly higher than that of the soils of the coastal plain. Most of the houses of Arequipa are built of a light rock called tuva which is of volcanic origin. This rock is 3 or 4 times as radioactive as the soil near Lima.

There is considerable variability of local radiation in some cases over small distances. According to Millikan,[6] the gamma rays on the Laurentian Shield near Churchill, Manitoba, give 0.8 ion cm^{-3} sec^{-1} atm^{-1} of air, or 12 mr yr^{-1}, while nearby the intensity on the glacial sand is 35 mr yr^{-1}. It may be of interest that the radioactivity on the icecap near Thule, Greenland, in August 1956 was less than 2 percent of cosmic rays.

A wooden building forms some shielding from local gamma rays. In my own house, the gamma rays on the first floor give 60 mr yr^{-1}, while in the back yard the intensity is 95 mr yr^{-1}. The rather high value of 130 mr yr^{-1} on the 23d floor of a major hotel in New York is presumably owing to the material from which the building is constructed.

The root mean square "noise" level of the total radiation given in figure 1 is about 160 mr yr^{-1}. To find the effect on the population, the local radiation must be weighted according to the population. This has not ben done. Perhaps it is fortunate that most of the population of the country lives where the radiations due to cosmic rays and local radiations are relatively low.

The dashed line near the bottom of figure 1 is taken from the summary reports on the Biological Effects of Atomic Radiation of the National Academy of Sciences.[7] Even though there is some error in the determination of this value, as well as considerable variation of fallout over the country, it is quite evident that manmade contamination is still small compared with the changes in radiation from one part of the country to another.

The data presented here are for gamma rays only, since the walls of the ionization chamber are too thick for beta rays to penetrate, either from naturally occurring or artificially produced radioactive materials.

H. V. NEHER,
Norman Bridge Laboratory of Physics,
California Institute of Technology, Pasadena.

The upper curve is the total dosage in milliroentgens per year. The first four points are various locations in Pasadena, Calif., in the years 1932, 1956, 1957. The lower curve is just that part of the dosage which is due to gamma rays. That is due to the radioactivity in the rocks. The difference between the two curves is the cosmic rays.

And as he goes to various places over the country, and over the world, you will notice that the very widest variation in these natural dosage rates.

In many cases the variation is due to the cosmic rays; in other cases it is due to change in the composition of the rocks.

[6] R. A. Millikan, unpublished results.
[7] Summary Report of the Committee on the Genetic Effects of Atomic Radiation, in Biological Effects of Atomic Radiation (National Academy of Sciences. Washington, D. C., 1956).

This presents the total dosage due to cosmic radiation and radiation from the ground and general surroundings but does not include the 21 milliroentgens per year from our own bodies, so to calculate the total exposure under the various conditions described, we should add this in.

Of course, houses shield from the ground radiation although not appreciably from cosmic rays—so that they are a diminishing effect. Professor Neher remarks that in his own house in Pasadena, the gamma rays on the first floor give 60 milliroentgens per year while in the backyard the intensity is 95 milliroentgens per year—just to give you a feeling for the effect of being inside as compared to outside.

Well, these dosages are all very large as compared to the 1 to 5 milliroentgens per year which we receive here in the United States from fallout, and we must put our experience from fallout in this context.

Now certainly our experience with these much larger normal doses shows us that the effects due to fallout radiation are relatively small.

The fallout facts are pretty well known and agreed. On the other hand, small as the effects are, they most likely do exist and the critical and essential question is, Are they tolerable?

This question, however, calls for a political or sociological—rather than a scientific—judgment, and I think it is important that this distinction be made.

Chairman DURHAM. Mr. Chairman?

Representative HOLIFIELD. Chairman Durham.

Chairman DURHAM. In the previous years' study up until 1945, there was no such thing as strontium 90?

Dr. LIBBY. There certainly was not, Mr. Durham, at all. There was no strontium 90. These data are important because they are before any contamination from weapons at all, you see. This radiation is still there, but it may be a little more difficult to be sure about it.

I should point out on that graph—you see that line that is right down near zero, that is the test fallout line.

Chairman DURHAM. Of course, that was made by a higher authority than man, the natural radiation.

Dr. LIBBY. That is right.

Chairman DURHAM. And since then, of course, we are adding to it by putting strontium 90 into the air streams.

Representative HOLIFIELD. Dr. Libby——

Dr. LIBBY. I want to make sure, Mr. Holifield, this graph is clear to everyone. This top line is the total. If you take a counter and measure these various places, that is what is there. This part [indicating] of it is from the rocks. The difference is the cosmic rays, and this [indicating] is the way it varies.

If you go to Pikes Peak, Colorado Springs, and so on, this is the way it varies.

Here is the test fallout down here, this dotted line. The smallness does not mean that test fallout is not important, that it is not a risk and a hazard, but it does mean that the test fallout is a relatively small hazard.

The first point is, since we have been living on this earth so long, we have some practical experience where commonsense can take hold, and we can say there is some limit just by the fact that we have not noticed these big things in our normal experience—there is some limit

to the bad effects from test fallout, and that is the only point I wanted to make.

Representative HOLIFIELD. Dr. Libby, to make the picture complete, is it not true that there is a very important difference in the bomb fallout which is not contained in either the cosmic rays or in the natural radiation, and that is the factor of strontium 90?

Dr. LIBBY. Yes, sir.

Representative HOLIFIELD. Which gets into the bones of people?

Dr. LIBBY. Yes, sir.

Representative HOLIFIELD. Where cosmic rays and natural radiation do not have that particular residual effect in the bones of people. So we have got another factor and, therefore , your analogy there must take into consideration also this new factor of strontium 90 that we must consider.

Dr. LIBBY. There is a great deal of truth in what you have said, Mr. Chairman. To comment on your statement requires a small technical remark.

Biological——

Representative HOLIFIELD. Why did not you make that statement first, Dr. Libby——

Dr. LIBBY. I wanted to——

Representative HOLIFIELD (continuing). Instead of making a statement which was susceptible again to a benign interpretation?

Dr. LIBBY. I want to tell you that the statement I have just finished making is true.

Representative HOLIFIELD. I know it is. Most of your statements are true, sir. But the point is this: That when once you have made those true statements, they are susceptible of misinterpretation, and if you follow up with a complete truth, it might give a more balanced effect in the layman's mind.

Dr. LIBBY. Let me do that. I think it will only take a couple of minutes. I will try to make it short.

A milliroentgen is an amount of energy absorbed by a unit amount of tissue. Now, depending on the kind of radiation the biological effect varies. The biological effect from 1 milliroentgen will be different for 1 kind of radiation as compared to another. This is called the relative biological effectiveness.

While it is true that we have never had strontium 90 before, we have had radiations which have essentially the same relative biological effectiveness, and have always had them, and those are the cosmic rays.

The cosmic rays, milliroentgen per milliroentgen, are within a small error the same as strontium 90, milliroentgen per milliroentgen. This is not true, Mr. Holifield, for gamma rays from rocks, but for the cosmic rays which make up a good fraction of the total natural exposure, they are just as damaging to the bone milliroentgen per milliroentgen as strontium 90.

Representative HOLIFIELD. Do they reside in the bone and of themselves make emissions, such as strontium 90?

Dr. LIBBY. No, no; but that is not necessary, you see. It is not the presence of strontium 90 in the bone that is damaging. You ordinarily have ordinary strontium in the bone. The bad thing about strontium 90 in your bones is that it emits radiation.

Representative HOLIFIELD. That is right.

Dr. LIBBY. So the cosmic rays in passing through the bone, as they do through all of your body, deposit in the bones energy which is in excess of the energy deposited by the present burden of strontium 90.

What I am telling you, Mr. Chairman, is that you can compare these two kinds of milliroentgens. You can say that if the milliroentgens from cosmic rays are large as compared to those from strontium 90, then the bone cancers and leukemias, and all the other things that may be caused by strontium 90 should follow even more from the cosmic rays. That is what I am saying.

In other words, the gamma rays you cannot compare, but the cosmic rays you can.

So when I went to the chart and said that about test fallout, I was telling you the truth in the sense that a good part of that total radiation is cosmic rays.

Representative COLE. Mr. Chairman?

Representative HOLIFIELD. Mr. Cole.

Representative COLE. I was going to ask Dr. Libby to explain that point on the chart which indicates that the local gamma radiation is almost identical with the radiation resulting from the fallout from the tests.

Dr. LIBBY. It is described in Dr. Neher's article. It is a local condition, but he does describe it.

I am sorry. He does not give a detailed description. I can give you a general answer, Mr. Cole.

Representative COLE. That will be good enough.

Dr. LIBBY. I am sorry but these effects are complicated, the way thorium and uranium occur. You see that low point is due to the fact that the uranium and thorium are missing there. Uranium and thorium occur every place—in all granite rock, for example. That is why you seldom can get away from it, unless you are living on a sand, or a formation which has through the accidents of geology had the uranium and thorium washed out of it. So in order to tell you why that point is low I would have to consider the local geology very carefully.

Representative COLE. Do you know the locality of the point?

Dr. LIBBY. It is on the Laurentian Shield in Canada. But the exact locality is not specified. However, the reference to the article is given, and we could look it up for you.

Representative COLE. Thank you.

Representative HOLIFIELD. Are there further questions, now?

Senator ANDERSON. Doctor, I want to come back to this question of clean weapons which has concerned me quite a bit, and to the article in the U. S. News where they asked you that question.

One question was:

> Dr. Libby, at one time the Commission announced they were developing a clean bomb, and then many scientists argued with you and criticized and even ridiculed the statement of the Commission. How do you account for that?

Your answer was:

> Well, in most instances, they were not privileged to know what it was.

Then the question:

> They did not know what they were talking about, possibly?

You said:

> I did not quite say that, but they were not apparently mamiliar with all of the details of it.

In your speech you referred to a clean weapon. Do you still feel we have a clean weapon?

Dr. LIBBY. Well, sir, I think we all know what the facts are. It is a question of how you describe the situation. We certainly have succeeded in cleaning them up to a great degree.

If you call cleaner "clean," maybe you are telling a small fib. But we certainly have a cleaner weapon, as you know.

Now, the question of the adjective which is applied to that, all I can say is that perhaps we have used the wrong adjective, and perhaps we should say "cleaner."

Senator ANDERSON. It is very important, because headlines all around proclaimed this clean bomb.

You said:

> We have taken the problems of radioactive fallout into consideration—

and this is on fallout, and this is why I bring it up—

> in our weapons development program and have developed and tested clean weapons, that is, weapons in which the amount of radioactive fallout per megaton of explosive is very greatly reduced.

Dr. LIBBY. Yes.

Senator ANDERSON. If I took a little of this coffee I have here, and poured it in that glass, it is dirty (pouring coffee into glass). Then, if I pour a little bit over there (pouring coffee in another glass), that is clean because the amount of dirt, to use your language, is very greatly reduced.

Would that be a fair statement? You cannot get a better example of what happened.

Dr. LIBBY. I think we know what the situation is. We have very greatly reduced the fallout per megaton of yield, and that is imporant.

Senator ANDERSON. I am only trying to say that a lot of our people have been reassured on this question by this so-called clean weapon, and it is still a dirty weapon. We have also learned how to make our weapons even dirtier than they originally were.

I think it is dangerous to use terms like "uniformity" when we mean "nonuniformity," and "clean" when we still mean "dirty."

Dr. LIBBY. I think our responsibility, Senator, is to tell the truth as best we can. I think that we must stay as close to it as we can. We are all clumsy in the use of language, and I am one of the worst. We may have chosen not exactly the right adjective, but I think we have explained it enough now so people know what it means.

Senator ANDERSON. I hope so, because I have seen many headlines talking about clean weapons. And knowing you and respecting you as I do, I know you would be the last one to want to mislead. I just hope no one will think there is no fallout damage when it comes to the use of weapons in atomic warfare, because it will come.

That is all.

Representative HOLIFIELD. Are there any further questions?

Representative COLE. Mr. Chairman, before releasing Dr. Libby, I would like to express my own compliment to him for the very fine presentation he has given to the committee this morning.

So far as time will allow, they have been complete answers, unequivocal so far as possible, sound, and dispassionate, and I think he has rendered a great help to the committee, and his work on the problems of fallout hazards has been most beneficial.

Representative HOLIFIELD. Dr. Libby, we will excuse you at this time, but we hope that you are able to be present for the general conference this afternoon at the conclusion of the testimony.

Dr. LIBBY. Mr. Chairman, the Commission meets at a quarter to three, and I will try my best to get back here at 4 o'clock. I understand it is at 4 you are having your meeting.

Representative HOLIFIELD. We are reconvening at 2 o'clock in this room, and we will continue with our witnesses until they are through, and then we will have the conference. I am not sure just when it will be.

Dr. LIBBY. I will come back as soon as I can, Mr. Chairman.

Representative HOLIFIELD. Thank you, Dr. Libby.

The committee will be in recess until 2 o'clock.

(NOTE.—Several articles and statements by Dr. Libby have been printed as appendix 1, p. 1459. An article entitled "Radioactivity in Man and His Environment," by Dr. F. W. Spiers, appears in appendix 2, p. 1671.)

(A paper entitled "Radiation Dose to Man From Natural Sources," follows:)

RADIATION DOSE TO MAN FROM NATURAL SOURCES

Robert A. Dudley [1] and Robley D. Evans,[2] Department of Physics, Massachusetts Institute of Technology, Cambridge 39, Mass.

I. INTRODUCTION

Man has always been exposed to high-energy radiation from cosmic rays and naturally occurring radioactive substances in his body and in his environment. Twentieth century society has brought about an increase in his exposure to such types of radiation, from such sources as commercial radium preparations, medical X-ray machines, and fallout. This increase has focused attention on the deleterious medical effects of high-energy radiation. Since the effects of this additional radiation on man are very difficult to determine when the effects are small, several methods of predicting them have been attempted. One of these has been to compare the magnitude of the artificial radiation with the magnitude of the natural radiation to which man has always been exposed.

The types of radiation associated with cosmic rays and natural radioisotopes include α rays, β rays, mesons, and γ rays. The first two are important only when their source is deposited within the body; the second two are important only for sources external to the body. These natural radiations are very similar in their biological effects to the β and γ rays of artificial sources, although quantitative differences, considered later, do exist between α rays and the others.

The organs of the body receive different exposures, depending chiefly on the degree to which various radioisotopes concentrate in them through either physical or chemical processes. Thus the skeleton is exposed to radioisotopes chemically similar to calcium. The intestines are exposed to all radioisotopes which enter the stomach, even if the element is insoluble and is not absorbed into the bloodstream. The lungs are exposed to radioactive dust retained from inhaled air. All organs are exposed to cosmic rays and γ rays from the environment.

Professional research experience: Use of radioactivity as a tool in various applications, particularly biological research; evaluation of Sr^{90} fallout problem while attached to United States Atomic Energy Commission; study of radiation dose to humans from natural and artificial sources. (Submitted by witness.)

[2] B. S. in physics, 1928, California Institute of Technology, Pasadena, Calif.; M. S. in physics, 1929, California Institute of Technology, Pasadena, Calif.; Ph. D. in physics, 1932, California Institute of Technology, Pasadena, Calif.; National Research Council fellow in physics, 1932–34, University of California, Berkeley, Calif. 1934 to present, physics department, Massachusetts Institute of Technology, Cambridge, Mass.: Assistant professor, 1934–38; associate professor, 1938–45; professor, 1945 to present. (Submitted by witness.)

On account of the many types of radiation and the many processes for deposition of radioisotopes in different organs, the general subject of the natural irradiation of man has many facets. The present study is confined to the natural radiation dose received by the skeleton and the gonads, these being the two organs of greatest interest in the case of fallout.

Many previous investigations can be drawn upon for pertinent data. In particular, reference may be made to the review articles of Libby,[1] Lowder and Solon,[2] Hultqvist,[3] and Spiers.[4] Although past studies by no means close the subject, reliable quantitative estimates of dose from the several important sources may now be given.

II. NATURAL IRRADIATION OF THE SKELETON

A. *Radiation originating within the body*

There are four natural isotopes which with their descendants contribute skeletal doses of comparable importance: potassium 40 (K–40), radium 226 (Ra–226), mesothorium (MsTh, or Ra–228), and radium D (RaD or Pb–210). In addition to these, there are many others (e. g., uranium, thorium, carbon 14) which are of negligible importance by comparison. The four important isotopes will be considered in turn.

K–40 emits β rays of 0.6 Mev. average energy and at a rate equivalent to 8.4×10^{-4} microcuries per gram of element K. Its γ radiation is of negligible importance compared with its β radiation in the case of K deposited in the skeleton. The abundance of K in adult bone is about 0.09 percent on a wet-weight basis.[5] From these data the dose rate to the skeleton may be calculated as about 8 mrad/year, where by definition 1 mrad$=10^{-3}$ rad$=0.1$ erg absorbed per gram of bone. Since the element potassium has a definite physiological role, it is controlled by the homeostatic processes of the body and is therefore expected to be found in the skeletons of all individuals in nearly equal concentration.

TABLE 1

Investigator	Description of samples			Equivalent RA content in bone ash

Na–226, the familiar Ra isotope, decays to the noble gas Rn by alpha emission. Rn itself is radioactive, decaying with a 3.8-day half life by alpha emission. Subsequent descendants emit alpha, beta, and gamma rays, of which only the alpha rays are important dose contributors. Po–210, the last of the three Rn descendants which emit alpha rays, is of minor importance in this sequence, as its formation is long delayed by the intervening RaD isotope.

Ra is found in the skeleton as an unessential trace element by virtue of its chemical similarity to Ca. Its most important source is solid food, although in some areas its abundance in drinking water exceeds its abundance in food. Many measurements of Ra concentration in human bone are available. The important published measurements are summarized in table 1. From these results a mean of about 4×10^{-14} microcuries per gram in chosen (the higher values being given less weight since they represent, in part, a study of a selected high region). Variations about this mean by a factor of 3 to 5 are found, depending on local conditions. The extremes of skeletal Ra concentration, as set by geography and other variables, cannot be accurately specified; however, it is unlikely that large population groups exist at concentrations differing from this mean by more than a factor of 10.

The magnitude of the radiation dose delivered to the skeleton by Ra and its descendants is influenced by the migration of the noble gas Rn out of the bone and its subsequent exhalation from the body. No data are available on percentage Rn retention from natural skeletal burdens of Ra, but at artificially elevated burdens the retention is about 25 to 50 percent. Presumably the natural situation is in this respect very similar. Taking the lower figure, one computes an average energy of about 11 Mev. dissipated within the body for each Ra disintegration. The mean skeletal dose rate is then found to be about 3 mrad/year attributable to Ra–226 (and its descendants produced within the body).

MsTh, a Ra isotope occurring in the radioactive series associated with Th, is itself a beta emitter of 6.7-year half life. However, it gives rise to several descendants which emit alpha as well as beta and gamma rays. While some of these descendants have such half lives or chemical properties that a possibility exists for migration out of the bone, it seems probable from animal experiments that, in fact, little such migration occurs.

MsTh has not yet been sought with sufficient thoroughness to provide good experimental data on its natural concentration in the skeleton. However, since it is an isotope of Ra–226, the dose attributable to it and its descendants may be reasonably accurately estimated from our knowledge of the Ra–226 situation. The activity of MsTh and Ra–226 in soil and water is on the average nearly equal. Therefore the MsTh/Ra ratio activity in newly formed bone will be nearly unity, while in older bone the ratio will be lower as a result of the shorter MsTh half life. Assuming nearly all the MsTh decay products remain in the bone, the energy ultimately delivered to the bone subsequent to each MsTh disintegration is about 30 Mev. Therefore MsTh gives a dose almost 3 times greater than an equal activity of Ra–226. In children the MsTh dose is expected to be about twice the Ra dose while in adults it will fall below the Ra dose. Averaged over the individual's life, MsTh (with its descendants) is expected to produce approximately the same skeletal dose as Ra–226, or about 3 mrad/year. This value is probably subject to approximately the same variations with geography as is Ra.

RaD is a member of the Ra series, decaying by beta emission with a 22-year half life. Its daughter, RaE, is a 5-day half life beta emitter, and its granddaughter, RaF (Po–210), is a 140-day half life alpha emitter. Only rough estimates of the RaDEF dose to normal bone can as yet be given. It is clear that RaD descended from Ra in the bone will accumulate with time, but in a quantity which is unimportant compared with the other members of the Ra series. In addition to the RaD generated from Ra in the bone, however, there is now good reason to expect a greater quantity deposited from food and water. These expectations are based on experimental measurements of stable Pb in the skeleton, from which calculations can be made for RaD. Preliminary unpublished measurements have been made of RaDEF in bones at the University of Rochester.[6] These measurements and calculations indicate that the dose from RaDEF is of the same order of magnitude as the dose from Ra, and it is tentatively assigned an average value of 3 mrad/year. More precise measurements will soon be available from several laboratories.

It is known that in the production of biological damage, the effectiveness of alpha rays, per unit of energy dissipated, is different from the effectiveness of beta rays, gamma rays, and mesons. This relative biological effectiveness (RBE) of alpha rays relative to the other radiations varies with the effect under consideration. In evaluating the toxicity of low dose rates to the skeleton, probably

[6] Black, Personal Communication (May 1957).

the most pertinent effect to consider is the production of bone tumors. Mouse experiments at Argonne National Laboratory on bone tumor production by beta rays (Sr-90) and alpha rays (Ra-226) suggest that the alpha ray RBE is about 4.[7] This number is here adopted, with recognition that at lower dose levels in humans the correct value could differ either way by as much as a factor of 2 to 4. A better estimate will be available from the dog experiments now in progress at several laboratories in the United States.

B. Radiation originating external to the body

Cosmic radiation at the earth's surface is composed mainly of mesons, gamma rays, and energetic electrons produced from the primary cosmic rays high in the atmosphere. The magnitude of the cosmic ray dose increases both with increasing altitude and with increasing geomagnetic latitude. The determination of this magnitude has been the subject of several series of observations. While the results are not all in close agreement, the discrepancy is not serious with respect to the accuracy here required. Taking the dose rate at sea level and high geomagnetic latitudes as given by Burch's review,[8] and the dependence of dose on altitude and latitude as given by A. H. Compton,[9] the skeletal dose rates of table 2 may be calculated. Using other data, slightly higher values are obtained.

TABLE 2

Altitude	Geomagnetic latitude		
	0°	30°	50°
0 feet	23 mrad per year	24 mrad per year	26 mrad per year.
6,600 feet	37 mrad per year	39 mrad per year	46 mrad per year.
14,300 feet	76 mrad per year	83 mrad per year	100 mrad per year.

There are three important sets of naturally occurring γ-emitting isotopes in man's environment: the uranium 238 (U-238) series, the thorium 232 (Th-232) series, and K-40. In the case of a man standing on flat ground, the contribution of skeletal dose from each series may be quite accurately calculated when its concentration in the ground is known. Furthermore, direct measurements have been made of the combined external γ dose and cosmic ray dose at several points.[3,4,10]

The concentration of the radioactive elements in ground is quite variable, tending to be highest in igneous rock (e. g., granite), and lowest in sedimentary rock (e. g., limestone) which is the more common at the earth's surface. Typical geochemical data [11] yield the skeletal dose rates attributable to each radioactive series as shown in table 3. (In this table, a factor of 0.7 has been applied to surface dose rate to give skeletal dose rate, thereby allowing approximately for shielding of one part of the body by another.) Considerable variation is found for the concentration of each series in such rock, but to some extent these variations in individual series cancel out. Some rocks (e. g., dunite) yield less than 1 mrad/year, while others (e. g., U or Th ores) give several thousand mrad/year. An example of the latter situation is found in the monazite sand region of south India, where about 100,000 people live in areas where the skeletal dose rate from Th and U in the ground is several hundred mrad/year.[12] However, these extreme conditions are surprisingly rare, and it may be assumed that only a very small fraction of the world's population is exposed from the ground to dose rates more than a factor of 2 outside the range shown in table 3.

TABLE 3.—*Skeletal dose rate in radioactive series*

Rock	U	Th	KK	Total
Igneous	17 mrad per year	22 mrad per year	27 mrad per year	66 mrad per year.
Sandstone	5 mrad per year	12 mrad per year	11 mrad per year	28 mrad per year.
Shale	5 mrad per year	20 mrad per year	28 mrad per year	53 mrad per year.
Limestone	6 mrad per year	21 mrad per year	3 mrad per year	30 mrad per year.

In buildings the dose rate from local gamma emitters will be somewhat altered from its value outdoors. In framehouses a slight reduction is expected, but by only a small factor since thin wood walls do not provide effective shielding. In houses built of brick or stone, shielding will be appreciable. However, the radioactivity in these materials (if of the same composition as the ground) will more than compensate for the shielding, and from purely geometrical considerations the dose rate inside will be approximately double that outside.

C. Summary of natural skeletal irradiation

The several components of skeletal dose rate previously listed are collected together in table 4. The unit now used is the mrem/year, where

$$\text{mrems} = \text{mrads} \times \text{R. B. E.}$$

Dose in mrems is thus equal to dose in mrads, except for α radiation where the R. B. E. is taken as 4. The values in table 4 are rough averages, and considerable variations in individual components are found for different population groups. However, these variations partially cancel, such that only a very small fraction of the world's population is expected to differ from the mean total exposure by as much as a factor of 3.

For comparative purposes, the following artificial dose rates may be considered: A fallout Sr–90 body burden of one one-thousandths the industrial maximum permissible concentration (roughly the present average in newly formed bone[13]) corresponds to about 3 mrem per year. The external gamma radiation from fallout is of the order of 5 mrem/year at present.[13] Medical X-ray dose rates to the skeleton vary from zero in backward areas to roughly the same magnitude as total natural dose rate in medically advanced societies.[14]

TABLE 4

Source of radiation:	*Skeletal dose rate (mrem/year)*
K^{40} (internal)	8
Ra–226 (internal)	12
MsTh (internal)	12
RaD (internal)	12
Cosmic rays (external)	30
Local gamma rays (external)	60
Total	134

III. NATURAL IRRADIATION OF THE GONADS

The only important internally deposited natural radioisotope in the gonad is believed to be K–40. Since it is an essential element having a definite physiological function, potassium in the gonads will be found at closely similar concentrations in all individuals. The mean value is approximately 0.2 percent,[4] giving a dose rate of about 18 mrads (or mrem) per year.

The gonads are exposed to the same external irradiation from cosmic rays and environmental gamma rays as is the skeleton, and the dose rates will be essentially identical.

The total mean natural dose rate to the gonads is therefore about 110 mrem/year, with variations from 1 region to another as associated with variations in cosmic rays and environmental gamma rays. These natural dose rates may be compared with the dose rates from fallout gamma radiation and medical X-rays as given above for the skeleton.

(Whereupon, at 1:10 p. m., the committee recessed, to reconvene at 2 p. m., of the same day.)

AFTERNOON SESSION

Representative HOLIFIELD. The committee will come to order.

Our first witness this afternoon is Dr. Ralph Lapp, a well-known physicist and author of books on radiation and related subjects. Dr. Lapp, we are pleased to have you before us this afternoon, and you may proceed.

STATEMENT OF DR. RALPH E. LAPP, WASHINGTON, D. C.[1]

Dr. LAPP. Thank you. Mr. Holifield, I received your invitation to testify before this committee while I was in Japan. I cut short my trip in order to attend the hearings. May I say that I appreciate very much this opportunity to appear here. I would like to add that I am very gratified that your investigations to date have thrown so much light on the problem of radioactive fallout.

I regret that the rate of accumulation of data in my files is so great that I have trouble in digesting it. I hope that during the next month I will have the time to analyze properly the amount of data that has been presented and that I hope I may be able to give you a later statement. I have been out of Washington for 3 months, and I have had trouble keeping up with things. Nonetheless, I am delighted to be here and testify before your committee.

Representative HOLIFIELD. We have permitted other witnesses to present additional data to substantiate their statements, and that same permission will be granted to you.

Dr. LAPP. I believe that these hearings will stand as a landmark in the history of our knowledge about this relatively new phenomenon.

Now I would like to add a comment about Dr. Libby. Appearing as I do after Dr. Libby, I would like to comment on his contributions to fallout. Dr. Libby has not only stimulated extensive research in fallout investigations such as Project Sunshine, but he has also taken the initiative in publication of his findings. I feel very strongly that he deserves a great deal of credit for his work on fallout. Were it not for Dr. Libby, we might well be confronted with a considerably smaller body of knowledge about fallout than we have today.

Mr. Chairman, I do not intend to read this entire document because it is too long, and I will skip over certain sections, with your permission, I might just mention that my interest in fallout extends over quite a period of years. I do not claim to be a great prophet with regard to the ultimate effects of radioactive fallout, since I think any examination of my publications about the Bikini shot of 1946 will

[1] Nuclear Science Service, Washington 7, D. C. Physics, Buffalo, N. Y., August 24, 1917. Strong Foundation fellow, Chicago, bachelor of science, 1940, doctor of philosophy (physics), 1946. Instructor, Chicago, 1940–41; research associate metallurgical laboratory, Manhattan project, 1943–44; division director, 1944; assistant to laboratory director, 1945; assistant laboratory director, 1946; Argonne National Laboratory, 1946; science adviser, General Staff Research and Development Division, U. S. War Department, 1946–47; Deputy Executive Director, Atomic Energy Commission, Joint Research and Development Board, 1947–48; Executive Director, 1948–49; head, Nuclear Physics Branch, Office, National Research, Department of the Navy, 1949–52; Director, Nuclear Science Service, 1953–; industrial consultant and lecturer, 1953–; assistant, Chicago, 1940–41. A. A., physical sociologist, cosmic radiation; meson; bursts; showers; mass spectroscopy; radiological safety; nuclear radiation physics. (From American Men of Science, 1955.)

show that I was not terribly impressed with the phenomena of radioactive fallout at that time. I had to learn the hard way.

I might say that my interest in radioactive fallout was really stimulated by the 1954 Bravo test at Bikini. This was the test which resulted in radioactive contamination of the *Lucky Dragon No. 5*, a Japanese tuna trawler.

Based upon results which were made available largely by the Japanese, I began the publication of a series of articles on fallout at the invitation of the editor of the Bulletin of Atomic Scientists, and with your permission I will put these into the record, if you so desire.

Representative HOLIFIELD. They will be received and filed with the committee.

(The series referred to follows:)

November 1954, Civil Defense Faces New Peril
February 1955, Radioactive Fallout
June 1955, Radioactive Fallout III
November 1955, Global Fallout
September 1956, The "Humanitarian" H-Bomb
October 1956, Strontium Limits in Peace and War

Dr. LAPP. I am dividing my testimony into four parts: general remarks, local fallout, remote fallout, and I am so bold as to add some constructive proposals.

Under "general remarks," I would say I believe public confusion about fallout will continue to increase unless scientists can provide a quantitative or semiquantitative evaluation of the various hazards associated with fallout. Precision is probably not possible due to the nature of the hazards, and we may have to be content with numbers which vary by a factor of 2, 3, or even 10. This committee, I believe, has already performed a valuable service in narrowing the range of estimates made by individual witnesses.

Regarding disagreement among the scientists, I think that the public may well conclude that if scientists cannot agree upon hazard, then all is confusion. It would be nice if the scientists could all agree upon a quantitative estimate of the hazard, which could then be given out to the public. I maintain two unusual circumstances have combined to produce the current confusion on radioactive fallout.

First, the urgency of our times has focused attention upon problems for which science did not have textbook answers. Available knowledge was inadequate and research such as Project Sunshine had to be initiated to provide answers.

Second, the ordinary process by which scientists argue out their answers was interdicted by the complexity of the problem and also by secrecy. Scientists outside the Atomic Energy Commission have full-time jobs, as do those inside, and could scarcely be expected to tunnel into the complexities of the problem in a few leisure hours.

With regard to the responsibility of the Atomic Energy Commission, I think that if we consider these factors, the Atomic Energy Commission has responsibility for providing the outside world with the facts about fallout as promptly as they become available.

Representative COLE. Mr. Chairman, I wonder if Dr. Lapp would mind interruption while his statement proceeds?

Dr. LAPP. I would welcome interruption.

Representative COLE. We all agree with your statement that the Commission should make revelation of its information about fallout as promptly as it becomes available. Do you have any feeling that the Commission has failed in that responsibility, except insofar as fallout material may have a direct hearing on weapons information?

Dr. LAPP. Mr. Cole, I believe that your qualification there makes it difficult for me to answer the question. When you say "except insofar as it may have bearing upon weapons information," you, of course, bring into play the difficulty. May I answer it as specifically as I can with regard to the question of radioactive contamination of large areas.

I believe that the Atomic Energy Commission could have made available to the public far earlier than it did its report of February 15, 1955.

This is the report on the effects of high yield nuclear explosions. It took almost a year from the time that explosion occurred until this, I would call it nonquantitative report, appeared. It has taken additional time until the weapons-effects handbook—I believe called The Effects of Nuclear Weapons—will appear, presumably this month.

It is my personal opinion, Mr. Cole, that could have been done more expeditiously.

Representative COLE. But if it had been published earlier than 10 months after the test, would you not agree that any report would have been based on conjecture rather than on facts?

Dr. LAPP. No, Mr. Cole, I think the facts about this particular incident were fairly well known as of May 1954, and I believe if one looks at the record of the investigation of this committee—I am referring to the investigation of March 24, 1955, called The Atomic Energy Commission-Federal Civil Defense Administration Relationship—in this report published by your committee, the Atomic Energy Commission has stated that it had a summary report of the radioactive effects of the Castle series of tests available, I believe, in May of 1954. So based upon that testimony by the Atomic Energy Commission, I would say that they had the facts.

Representative COLE. The Commission, as you know—either the President or the Chairman of the Commission—did shortly after that test give a generalized report on the results of the test.

Dr. LAPP. Yes. It occurred, I believe, in my memory serves me correctly, on March 29 or 30, 1954.

Representative COLE. Some time in March.

Dr. LAPP. Yes. I personally do not feel that report was an adequate or quantitative evaluation of the hazard.

Representative COLE. Of course, it was not. It was not intended to be. But it was a general report to the public as quickly as general facts could be made known.

Dr. LAPP. It was a general report.

Representative COLE. As to the detailed lessons based on facts as they were observed might necessarily involve a period of time. It would seem that a period of 11 months, considering the importance of the subject under study, was not inordinate.

Dr. LAPP. I think we may disagree how long would have been required for this. I might say, Mr. Cole, if I am permitted a moment to look into my own notes here—that so far as I personally am concerned,

based upon data made available from the Japanese, I was able to publish in November 1954 in what I would call semiquantitative form an analysis of the hazard, and again in 1955 I was able to publish in the Bulletin of Atomic Scientists in February—I am sure I have it here, but it just escapes me—let me quote from memory.

Senator ANDERSON. I think I have a full file of the bulletins.

Dr. LAPP. It is the February 1955 issue.

Senator ANDERSON. That is probably the one I do not have.

Dr. LAPP. In this issue I believe I presented a quantitative estimate of the hazard which was more detailed in numbers than was the Atomic Energy Commission's release of February 1955. The situation, I realize, is difficult if one wishes to make a precise statement. But I do not think it was a precise statement that was needed. I believe something which would indicate the general magnitude of the hazard which civil defense faced would have been important.

By the way, I will come to this point in connection with later testimony.

May I continue?

Representative HOLIFIELD. You may proceed.

Dr. LAPP. I believe, then, that scientists, technicians, and officials of the Atomic Energy Commission must present reasoned and careful estimates of the hazards based upon factual knowledge. Reckless or nonsubstantiated statements do a disservice to the Atomic Energy Commission and to the Nation.

Representative VAN ZANDT. Dr. Lapp, you say reckless or nonsubstantiated statements do a disservice to the AEC and to the Nation. You make this statement under the title "The Responsibility of the Atomic Energy Commission." Are you charging that the AEC spokesmen made reckless or nonsubstantiated statements?

Dr. LAPP. I believe that the examples I have given here, particularly when we have a man like Dr. Richard Doan coming to Tokyo only last month stating that the bomb test did not have the slightest possible effect—I would be happy to place the entire quotation in the record—upon humans, that is nonsubstantiated. I believe it constitutes what may be regarded in the light of the great world importance of atomic energy as amounting to a reckless statement.

I have not charged that Dr. Libby made a reckless statement here when he said, "However, as far as immediate or somatic damage to health is concerned, the fallout dosage rate as of January 1 of this year in the United States could be increased 15,000 times without hazard."

Representative VAN ZANDT. Dr. Lapp, do you have all available information in this field?

Dr. LAPP. I have such information as is available to the public.

Representative VAN ZANDT. But you do not have the reservoir of information available that Dr. Libby has, do you?

Dr. LAPP. If I am to believe from Dr. Libby's testimony this morning that it was all unclassified, I would say that I must have.

Senator ANDERSON. It is either classified or you have it?

Dr. LAPP. Yes. I am sorry you are asking me something that is difficult for me because I simply do not know whether or not there exist things which are buried in secrecy.

Representative VAN ZANDT. I am not worried about classified information. I regard Dr. Libby as a member of the Atomic Energy Commission and therefore having at his fingertips all possible informa-

tion with access to AEC files. Therefore, when he makes a statement he must certainly make it based on the most comprehensive information available.

Now, I am asking this question: Do you have comparable information?

Dr. LAPP. No, sir.

Representative VAN ZANDT. By making the critical statement regarding the AEC spokesmen, in effect you compare yourself with Dr. Libby from the standpoint of availability of information. Therefore, it amounts to this, does it not, that it is simply your own opinion?

Dr. LAPP. It is my opinion based upon the facts which Dr. Libby has presented.

Representative VAN ZANDT. That is all, Mr. Chairman.

Dr. LAPP. I might say I can only go on what Dr. Libby has stated plus my knowledge of science and physics.

Representative PRICE. Mr. Chairman, may I ask Dr. Lapp a question?

Representative HOLIFIELD. Yes.

Representative PRICE. Is it merely your personal opinion, or is it your opinion based not only on information made available to you, but on consultation and association with other scientists?

Dr. LAPP. I have consulted with many scientists. I may not say in the specific preparation of this document because I was working until the early hours this morning doing this. I have in the past number of years consulted with many scientists of considerable note. I do not pretend to speak for scientists. But I might say this, Mr. Price; I have been encouraged by scientists.

Representative PRICE. You do not feel that you are alone in these opinions?

Dr. LAPP. I am alone right now, sir.

Representative PRICE. I do not think you have been alone. I think others have testified pretty close to the testimony that you started out to give here. I do not think you are alone.

Dr. LAPP. I would like to make this statement, Mr. Price. I have come here today to try to present such observations as I can to be of help to this committee. I do not want to be put in the position of challenging every statement that Dr. Libby makes.

Representative PRICE. I did not assume that you were challenging everything. The point I wanted to draw out was whether or not these were just strong personal convictions on your part, or whether or not you had arrived at your conclusions not only through the examination of the material furnished to you but through your personal studies and association with other leading scientists not only in this country, but in other parts of the world.

Dr. LAPP. I have recently consulted with scientists in Japan. I might say that one of the useful things that I accomplished in discussing these problems with the Japanese was that I think I explained some of the strontium measurements to the Japanese and tried to reconcile Dr. Libby's data with their own. I think it was useful because many of their figures were quite high as compared with Dr. Libby's. Although I am not yet sure that they believed everything I have said, I have been in correspondence with them since and I have tried to bring about some agreement in this field.

Again, I state that I personally owe a great debt of gratitude to Dr. Libby as I think the country does in providing us with these very valuable data.

Representative PRICE. I think we all agree with you on that. I think you were interrupted before you were permitted to give the examples that you were going to give on statements you referred to as perhaps "reckless" statements.

Dr. LAPP. I think we must interpret this and perhaps qualify it somewhat. That is, we are dealing now with statements made to the public. This is an area in which I have had some experience, namely, in the translation from the world of megacurie and the megaton into the world of ordinary understanding. I think Congressman and Senators know how difficult this translation can be. Dr. Libby's speeches have not always been masterpieces of simplicity for the press to understand. I have in many cases attempted to translate these speeches so that they might be more useful.

Senator ANDERSON. Doctor, now that you have had a chance to refresh your memory as to your fallout data, do you find you reported in the February 1955 issue of the Bulletin of the Atomic Scientists?

Dr. LAPP. Thank you. It was in the February issue of 1955 that I presented a quantitative estimate of the radiation exposure. I believe this curve showing cumulative dosage from fallout agrees with the data which are now presented some 3 years later in The Effects of Nuclear Weapons. I am going to testify about this.

Representative HOLIFIELD. You made that chart without access to classified information?

Dr. LAPP. The basis of making this chart was, if I may be permitted—this is a complex technical matter—to give you a complete explanation.

Representative HOLIFIELD. Make it simple.

Dr. LAPP. I have here the reports of the Japanese scientists. These are called Research in Effects and Influences of Nuclear Bomb Test Explosions. I want to point out that this has been published only recently, but it contains many of the scientific papers of 1954 upon which I based my deductions.

These reports might just be illustrative to show how much other countries are publishing. These reports are the research in the effects and influences of nuclear bomb test explosions in two volumes compiled by the Committee on Compilation of the Report on Research and Effects of Radioactivity, published in Japan for the Society for the Promotion of Science. There are about 1,800 pages of data in these reports.

Representative HOLIFIELD. The chart that you gave in February 1955 has stood up, then, against challenge, has it?

Dr. LAPP. I believe so. I have discussed this with Dr. Eugene Wigner, who is a scientist of outstanding note. We were much concerned about the tail of the curve. This tail of the curve is quite important because it is upon the tail of the curve that the long term persistence of radioactivity will depend. At the time I talked with him, Dr. Wigner had his doubts about how this tail may be extrapolated.

My own feeling is the recent data of Dr. Dunning, contributed to this committee, support this curve.

Representative COLE. Dr. Lapp, you will concede that your report of January 1954—or is it February?

Dr. LAPP. I think it came out in February.

Representative COLE. That was the same month that the Commission's report came out.

Dr. LAPP. Yes, Mr. Cole.

Representative COLE. But your report was based on studies of exposure to the Japanese fishermen.

Dr. LAPP. Yes.

Representative COLE. Whereas, that was only a part of the persons who were exposed to radioactivity. Is that not correct?

Dr. LAPP. That is correct, Mr. Cole.

Representative COLE. There were other people, the Marshallese, who were also exposed.

Dr. LAPP. That is true, but the data which I am concerned with is not data on people, but rather the actual number of curies of radioactivity deposited on the surface of the Lucky Dragon.

I might say, by the way——

Senator ANDERSON. Your report came out in the February issue which reaches the subscribers ahead of the first of the month. The Commission report came out in March and followed by a considerable period of time the publication of the data that you have there, did it not?

Dr. LAPP. I believe there was a difference in time of about 8 days. I prepared this, by the way, in December of 1954. I again received a tremendous amount of help from Dr. Libby's first speech of December 1954. It was very useful to me. I really feel that Dr. Libby has contributed immensely to this whole phenomenon of fallout.

Representative COLE. Mr. Chairman, before Dr. Lapp leaves this question of the responsibility of the Commission to make factual publication of its information, Dr. Lapp has indicated three examples which in his opinion represent a failure to fulfill that responsibility of frank and honest statements. He has characterized them as reckless and nonsubstantiated by the facts.

Dr. LAPP. Not all the statements.

Representative COLE. I notice you made an exception with respect to Dr. Libby's statement that it was not reckless, which leaves the conclusion that his statement nevertheless was unsubstantiated by the facts.

Dr. LAPP. With respect to that, Mr. Cole, I would wonder whether or not in the light of the testimony that has been received by this committee that Dr. Libby would still wish to subscribe to the statement that the fallout dosage rate as of January 1, 1955, in the United States could be increased 15,000 times without hazard.

Representative COLE. I am not seeking to argue with you. I am simply trying to establish clarity in the record.

Another question is this. These three examples which you have enumerated, do they constitute the only instances which have come to your attention where employees or representatives of the Commission have made statements on this subject which you feel were perhaps reckless to some degree, or not substantiated by the facts?

Dr. LAPP. No, Mr. Cole. I would have to go through my files. I believe there are many more.

Representative COLE. But would you agree that these are the most glaring instances of recklessness on the part of such people?

Dr. LAPP. Until I really combed my files and did a thorough job I can't answer the question.

Representative COLE. It would seem from the fact that these impressed themselves on your memory, and that you have cited them would indicate that they were the most extreme instances.

Dr. LAPP. No, I would not believe that. I think I cite them because they were readily at hand when I prepared this testimony.

Representative COLE. On this point, Mr. Chairman, it would seem to me that in fairness to these individuals whose responsibility has been questioned in this regard—Dr. Eisenbud and Dr. Doan—they should be given an opportunity to give whatever explanation they may have by way of defense against the charge of having issued a reckless and unsubstantiated statement.

Representative HOLIFIELD. I will respond to that. They will be given this opportunity if they care to.

Representative VAN ZANDT. Dr. Lapp, I am not doubting your ability as a physicist nor am I challenging your right of opinion, but for the first time during the course of these hearings we have the integrity of a Government agency challenged. That is what it amounts to. It has changed the complete tone of these hearings as far as I am concerned. We are not sitting here as an investigatory committee. We are sitting here for the purpose of trying to find the answer to this radiation problem. I think you would make a great contribution to these hearings if you would delete from your statement that charge you have made against the AEC and certain physicists employed by them.

Senator ANDERSON. I thought we were going to hear their replies to the charge. I think if Dr. Eisenbud will come in and prove as they laid down these criteria of proof the other day, that fallout to date from all tests would have to be multiplied by a million to produce visible deleterious effects, except in areas close to the explosion, that it would be very interesting.

Dr. Libby says he does not know what will happen when this comes out of the stratosphere. If Dr. Eisenbud would give us a short statement proving that it will have to be increased a million times, I think that would be very interesting. It would contradict a great deal of testimony from the Atomic Energy Commission itself.

Representative COLE. Mr. Chairman, I would point out by way of important emphasis that this statement of Dr. Eisenbud was made on March 20, 1955.

Dr. LAPP. Yes.

Representative COLE. So whatever response he may have to make by way of justification or explanation will have to be predicated as of that day, and not as of today.

Dr. LAPP. I would like perhaps to amplify this one bit, that is, that when I talk of the use of the word "reckless," there, I am speaking in terms of how the noneducated public will interpret statements made to them. That was my only purpose. I am not challenging the integrity of those people.

Representative COLE. Dr. Lapp, would you assert that the Commission's spokesmen in the scientific field were the only scientists who have made reckless and unsubstantiated statements on this problem?

Dr. LAPP. I would not. Reckless statements have been made by scientists who are not in the Atomic Energy Commission.

Representative COLE. Would you also say unsubstantiated statements were made by scientists who are not in the Atomic Energy Commission employ?

Dr. LAPP. I would readily agree to that.

Senator HICKENLOOPER. Mr. Chairman, may I ask Dr. Lapp, have you examined the full statements of Dr. Eisenbud and Dr. Libby and Dr. Richard Doan that you referred to here?

Dr. LAPP. Yes, sir.

Senator HICKENLOOPER. So it is based on that examination of the full statement that you quote out of context here?

Dr. LAPP. Yes, sir.

Senator HICKENLOOPER. And draw your conclusions that these add up to what you call reckless statements?

Dr. LAPP. Yes.

Senator HICKENLOOPER. I think perhaps one might argue that there is a degree of recklessness in dogmatic statements even by yourself in drawing these conclusions, not having been closely associated with the investigation of the data involved, and I rather question the advisability of the use of the word "reckless" in this rather difficult and quite ramified and uncertain field.

Senator ANDERSON. Dr. Lapp, would you not agree with me that there is a possibility that Dr. Eisenbud might not have been correctly quoted in the newspapers? I say that because Dr. Eisenbud gave us what I regarded as extremely fine testimony in his appearance before the committee. I thought it was scientifically based and carefully put together, and you have spoken very highly of Dr. Libby. I share your high regard for him, and I would hope that you might express to me how you feel about Dr. Eisenbud. I think he is a very capable and fine man. I hope that would sort of find some response in your system also.

Dr. LAPP. I was much impressed with the statement he made before this committee. The statement he made was in the Sunday News for New York of March 20, 1955. I believe that this illustrates one of the problems, Mr. Anderson, of the scientists and the press. He is really responsible for being careful in issuing statements to the press. I am not in any away attempting to attack the integrity of any people. I merely point out the impact which this will have upon the public.

So far as world interest in fallout is concerned—I will try to read this quickly—the committee may be interested in my observation that fallout has become an acute weapon of propaganda. For example, I found the Japanese scientists are actively studying the radioactivity of their tea, because of the assertion from the Chinese mainland that Japanese tea is radioactive. Apparently fallout does not occur in China. Some people in Japan are so keenly aware of fallout——

Representative HOLIFIELD. I think you should clarify that facetious remark, because in the print your manner of delivery might create the impression that you have said that it does not.

Dr. LAPP. I am sorry. It seems to me that here is an example of how radioactive fallout can be used as a weapon of propaganda in which a country which might stand to gain from its sale of a product accuses another country of having radioactive tea, and forces that other

country to engage in fairly laborious research project to find out how radioactive their tea is.

I visited this laboratory where tea was analyzed and saw the vast quantities of tea tested for radioactivity. I cite it merely as an example of how this can be used.

Representative COLE. What were the results of those tests?

Dr. LAPP. The tests are still underway. I believe the results will be given out within the year. I did not find any unusual radioactivity from the contact I had with Dr. Shiokawa. Some people in Japan are so keenly aware of the fallout that they actually take showers after being out in the rain.

There was a great public outcry against the British Christmas Island tests, but there was no great demonstration against the Soviet tests. It seems to me that this is a great victory for psychological warfare experts when they can induce selective sensitivity to fallout.

Representative COLE. Dr. Lapp, since you were there in Japan at the time of these tests or immediately prior to the tests, can you account for the fact that there was such a striking demonstration against the Christmas Island tests and yet there was no equal or even slightly proportional demonstration against the Russian tests?

Dr. LAPP. I might point out in all fairness that so far as the Japanese Government was concerned, they did protest the Soviet test, too, but as far as the public demonstration was concerned, I know of no such demonstration against the Soviet test. I think, however, one can give a partial explanation for this. This is in the fact that the Japanese people were immensely affected by the radioactive fallout in the fishing areas of the Pacific. After the accident of March 1, 1954, the Japanese Government went to considerable effort and expense to monitor the fish supply, which is a great source of protein for the Japanese. I think therefore they associated with the Christmas Island tests an effect upon their food supply.

Representative COLE. If that is so, how do you account for an equally demonstrative representation against the tests here in Nevada?

Dr. LAPP. I was not aware that they had such an outcry.

Representative COLE. You must have been aware that some Japanese people stormed the gates of the American Embassy in Tokyo in protest against the Nevada tests.

Dr. LAPP. I am sorry. I was traveling about Japan a good deal and perhaps I missed this one, Mr. Cole.

Representative COLE. This only occurred within the past month.

Dr. LAPP. I see. I did not know about this.

Representative COLE. Yes.

Dr. LAPP. I cite my reason as one factor.

Representative COLE. It is understandable that the Japanese people should be unusually sensitive to the hazard of radioactive fallout. That is very understandable. But it is difficult for me to understand why they should distinguish between the hazard of the British or American fallout without apparent protest to the hazard from Russian test fallout. Do you have any explanation for it?

Dr. LAPP. I could not profess to be extremely competent in this regard. I believe, however, there is a Communist Party at work in Japan. I believe that they use radioactive fallout as a political weapon. In fact, I believe that in the case of the survivors of the

Lucky Dragon, that their families were visited by representatives of the Communist Party who promised them money by way of being helpful. To my knowledge they never showed up with the money, but they promised them money.

Representative COLE. Were you not told when you were in Japan, as I was, that the newspaper reports of the Russian tests indicated to the Japanese people that the Japanese scientists had detected some unusual turbulance in the atmosphere? It was characterized as such, with no direct reporting that this was radioactive material. It was simply tagged as an atmospheric disturbance, whereas the press described the British and American tests as radioactive contamination of the air.

Dr. LAPP. I think they are probably allergic to American bomb fallout. This is rather interesting, in view of the fact that the data given to me by the Japanese show that some 70 percent of the total gross activity of the fission debris falling upon Japan is of Soviet origin, 20 percent from the Pacific tests and 10 percent from the Nevada tests.

Representative COLE. That was given to you by Japanese scientists?

Dr. LAPP. Yes.

Representative COLE. Have you ever seen that conclusion published in the Japanese newspapers?

Dr. LAPP. I gave a number of interviews when I was in Japan, and I pointed this out, but I unfortunately do not read Japanese, and do not know whether they reported it. It may have been. I stated the fact that there ~~is~~ greater fallout on Japan from Russian tests than from United States tests or United Kingdom. I am unaware that it was published. It may have been.

Representative COLE. This is a rather remote and roundabout route by which to provide these conclusions for the information of the Japanese people. I can hope that the Japanese reporters who are present here today may report to their respective newspapers published in Japan the conclusion which was given to you while in Japan, a conclusion by Japanese scientists—that their tests of the contamination of the atmosphere over Japan was caused 70 percent from the Russian tests and the balance from American and British tests.

Dr. LAPP. I think, Mr. Cole, I hope that these facts are reported in the Japanese press. I have reason to believe they will be. I think it is entirely reasonable that the fallout upon Japan should be predominantly from Russian tests because of the greater tropospheric fallout which Dr. Libby explained this morning. The greater tropospheric fallout from these tests will occur from the Russian tests. Because of the fact that they are in the air mass trajectory from the Soviet test region, this fallout will occur upon Japan sooner than upon other parts of the world. Because of the freshness of the fallout, there will be a greater radioactivity.

Representative COLE. That being a scientifically provable fact, then, is it not appropriate that the Japanese should be far greater concerned over Russian tests and the hazard of Russian tests than the tests by the United States and United Kingdom?

Dr. LAPP. If I were a Japanese I certainly would be.

Representative HOLIFIELD. It is not strange, as far as I know that the Atomic Energy Commission has never revealed this very important fact, and that the first knowledge I have of it is as of today? If

they have revealed it, I am unaware of it. We are being subjected to propaganda as you have stated by the Communist Party seizing on the part of this technical information which is to their advantage, and using it in Japan. Why is not this a piece of scientific fact that could be used on our part and let the world know that 70 percent of the fallout on Japan comes from Russian origin, if that is a true fact.

Dr. LAPP. Mr. Chairman, I am trying to strain my memory to remember this, but I believe that the National Academy of Sciences report contains data on relative fallout. I am trying to remember if it was on Japan. I think that it does contain data on this, but it is probably buried in the scientific literature.

Representative HOLIFIELD. I have read the report fully, and if it is in there, I have either forgotten it or I could not understand it, the way it was stated.

Dr. LAPP. I do not think it was in the summary or general report, but was in the greater compilation of the appendix, the physical measurements.

Representative HOLIFIELD. But a report of the American Academy of Sciences is not a publicized report of the Atomic Energy Commission.

Dr. LAPP. I might say this. I cannot remember any Atomic Energy Commissioner making a point of this in his speeches. I read most of the speeches quite carefully. I do not remember this being made.

Representative COLE. You do not know whether this information has been made available or known to the Commission, do you?

Dr. LAPP. I could not state positively.

Representative COLE. Of course, if the Commission had wanted to or happened to it could have found the same information which was given to you. I do not question that. But there is no evidence, or is there, that the Commission had this information?

Dr. LAPP. I am sorry, I am not competent to discuss that.

Representative COLE. Mr. Holifield referred to this conclusion of yours, or this information which was given to you as having an element of propaganda. I am sure he did not intend to use that word in the strictest sense, because this information in my opinion is not propaganda. This is a statement of the scientific facts as resulting from the examination of competent Japanese scientists.

Representative HOLIFIELD. I will accept the gentleman's amendment, if he will allow me to substitute the word "publicity" in the place of "propaganda."

Representative COLE. Yes. It should be publicized generally, and widespread, and that is why I am talking about it as much as I am in the hope that the reporters who are present will make certain that it is publicized fully and in all of the newspapers in Japan.

Representative HOLIFIELD. I had assumed that Project Sunshine was all over Japan, too, and we knew about this.

Representative VAN ZANDT. Mr. Chairman, I would like to ask Dr. Lapp another question.

Dr. Lapp, the Japanese scientific documents you have at your elbow, have you gone through them as yet?

Dr. LAPP. I have gone through a great many articles, yes. Some of them did not interest me too much, so I skipped over them. I have gone through a great many.

Representative VAN ZANDT. Dr. Lapp, do you think all the information contained in those Japanese documents is original or has somebody borrowed the information from the American scientific family?

Dr. LAPP. I would say that much of it is original and of course scientists borrow wherever they get the information. That is the nature of science. It is an international community. There are a great many references in each paper to the United States reports, and to other nations as well. I think that the United States reports predominate.

Representative VAN ZANDT. In other words, the volumes contain much United States data?

Dr. LAPP. No, they reference United States data. For example, if we have a radiochemical technique for detecting a particular radio element, then they would use the technique and reference this. I want to point out, however, that the Japanese scientists, despite the fact that they are not many in number as compared with other nations, have quite a history of excellence. I had the great pleasure of talking with Professor Kimura only two Sundays, ago, and he was very kind to show me some of his original work, and I know it was of very high quality.

Representative VAN ZANDT. Dr. Lapp, have you had made available to you a copy of a Russian scientific document entitled, "Preliminary Data on the Effects of Atomic Bomb Explosions on the Concentration of Artificial Radioactivity in the Lower Atmosphere and Soil"?

Dr. LAPP. I have not. (See p. 1209.)

Representative HOLIFIELD. It was just called to my attention by the chairman that one of our outstanding scientists in California is an American Japanese.

Dr. LAPP. The Japanese scientists are particularly competent in the field of theoretical physics. One of the greatest theoretical physicists in the world is Professor Yukawa, famous for his discovery of the meson.

It is inherent in the very nature of the biological research into the effects of radioactivity upon humans that a high degree of accuracy is not attainable, especially on human experience basis. As Dr. Langham, of the Los Alamos Laboratory, has testified, human experience with retention of radium 226 is the basis for setting upon a maximum permissible concentration for radiostrontium. Yet our actual experience is confined to a small sample of acutely exposed individuals and a small sample of less acutely exposed people.

Actually, our concern should focus not upon acute effects in man, which are highly unlikely from peacetime bomb testing, but rather with the chronic, debilitating, long-term effects from irradiation of humans. We must be conscious of the need to appraise long-delayed effects, say 50 years after entry of radio elements in the body. Here our knowledge is quite limited.

SECTION F. RADIATION LIMITS FOR A GLOBAL POPULATION

I would like to stress the fact that consideration of safe limits for irradiation of the world's population is essentially a new problem. Prior to the awareness of global fallout, the International Commission on Radiological Protection made its recommendations for those who would be exposed to radiation in pursuit of their occupation.

Such groups initially were numbered in the hundreds and then in the thousands as atomic energy came of age. Individuals within such groups were healthy adults exposed to known and restricted hazards; they were subject to administrative controls and medical supervision.

In setting up limits for a total population, we must take into account the varying radiosensitivity of individuals, the complete spectrum of age, the persistence of the hazards, the lack of medical control, the varying degrees of health of people, and the variety of their diet. Yet it was not until last year that the Atomic Energy Commission introduced the difference between an occupational MPC and a global MPC into its releases on fallout.

May I explain that briefly? Dr. Libby, in his speeches referred always to the MPC. I am not accusing Dr. Libby of deliberately trying to mislead anybody, but, from the standpoint of the ordinary layman reading these things, there was no distinction between a maximum permissible concentration for occupational workers and for the world population. I think this is one of the things that is necessary when you are putting information out to the public—that you must distinguish between these different units.

Representative COLE. Why is that, Doctor? What is the difference whether the individual absorbs or is exposed to the maximum MPC in an atomic plant or as an employee or whether he is exposed to it outside. Why do you feel that a distinction should be made?

Dr. LAPP. I think the distinction should be made on the basis, first of all, of the difference in radiosensitivity of the individuals. You are dealing with the total population now when you are dealing with the global risk. You are dealing with people who have no medical supervision. You are dealing with people who are of different ages. I believe that the International Commission on Radiological Protection recommends a factor of 10 and others believe it should be more—a factor of safety—when dealing with the total population than when you are dealing with the small population, the occupationally exposed population. These are the recommendations of the international body on the subject.

In view of the nature of our knowledge and the totality of the sample with which we are dealing, I would urge a big factor of safety in setting limits to bomb testing. It would be tragic to find someday that we had erred in setting the limits.

Perhaps I might explain, in response to Mr. Cole's question, the probabilities involved here. Supposing that the probability of damage were only one in a thousand and you only had 10 people working in the laboratory; this would be a small risk for 10 people. But if you had one in a thousand and apply the same statistics to a total population of 2 billion people, obviously, you have a very different situation. It is part of the philosophy that goes into establishing such figures.

Representative COLE. When you say, in your opinion, that we should set a big factor of safety, don't you mean that we should set a very low factor of safety in order to be on the safe side?

Dr. LAPP. Perhaps my language is not clear there.

Representative COLE. You mean the same thing.

Dr. LAPP. Yes.

Representative COLE. We should be ultracautious in fixing a factor of safety.

Dr. LAPP. Yes.

The Soviet nuclear tests: I felt that the committee might be interested in learning some miscellaneous data I picked up in Japan. I learned that the Japanese scientists collected sufficiently active samples from the Russian tests to perform radiochemistry upon the bomb debris. I was informed that five Soviet tests produced a fallout on Japan from which scientists measured and identified the presence of radioisotope uranium 237. The Soviet explosions were characterized by such fallout that they were judged to be in the megaton range. These estimates are subject to considerable uncertainty, but one authority told me that he estimated that at least 2 bomb yields were in the range of 10 megatons.

Two Soviet nuclear tests were observed to originate in the Arctic region, whereas the remaining tests took place in a region estimated to be the Ozero Balkash, which is southeast of the new coal area of Karaganda. The air-mass trajectories from central Siberia frequently sweep across the islands of Japan, especially Hokkaido. They also produce tropospheric fallout over the United States, as well. Here in Washington you could swipe a Kleenex over a car top and cause a Geiger counter to respond. Perhaps that is a qualitative statement, because the normal counting rate of the counter is 20 counts a minute, and the counter may go up several times over that. But it was readily detectable by even such a simple analysis as this.

Representative VAN ZANDT. Dr. Lapp, that last statement you make; is that a fact or is it just hearsay?

Dr. LAPP. I was told this by one of my scientific colleagues, since I was not here at the time. I have no reason to doubt it.

Representative VAN ZANDT. Then we are getting it secondhand.

Dr. LAPP. Secondhand, but I can give you the source, if you wish. I have seen the measurements done myself. The presence of uranium 237 in the Soviet fallouts proves that the Soviets have achieved a compound fission-fusion or so-called multiple-stage weapon. According to my information, this was first accomplished in September 1954.

Representative COLE. First accomplished where?

Dr. LAPP. In the Soviet Union. The next statement has already been made.

I would like now to talk about the problem of local fallout. I am not going through all of section A, because what I am doing there is trying to explain a term which I coined some time ago in order to eliminate confusion in popular translation with the megacurie. The term I used is the "eternity roentgen" per square mile. It turns out that this particular compound unit is extremely easy to use in estimating the roentgen exposure of people in a bomb area. I will not go through all of this.

Could I have the chart of Dr. Shafer put up? (See p. 119.)

Last week Dr. Shafer testified before this committee about an attack of 2,500 megatons of bomb yield upon the United States, and specified that they were surface burst dirty weapons. By dirty it is meant that the ratio of fission to fusion is high. I assumed that 2,000 tons of fission products deposited locally. This I calculate as 12 billion roentgens per square mile.

Representative COLE. You have characterized these as dirty weapons, Dr. Lapp. How would you evaluate the content or force of a weapon which might be called a clean weapon? As you know, there

has been a considerable discussion of the maining of the words dirty versus clean, clean versus cleaner. You have used the words "a dirty weapon." Are there degrees of dirtiness?

Dr. LAPP. Yes. I would estimate the degree of dirtiness as the ratio of the fission to the fusion release in the bomb.

Representative COLE. So that in your opinion it is possible to fabricate a weapon which is clean.

Dr. LAPP. Relatively clean. To answer the question precisely, the question would be whether or not you could fabricate a weapon in which there were no fission products.

Representative COLE. You could not do that.

Dr. LAPP. This I do not believe is possible. So you can fabricate a cleaner weapon.

Representative COLE. Would you conclude that it is possible to fabricate a weapon which is so clean that dirtiness is not of great importance?

Dr. LAPP. I do not have the facts on which to answer that question.

Representative HOLIFIELD. No one else has come before us who had the facts to answer that question. Dr. Graves answered the exactly opposite. He said there is no such thing as a clean weapon. There are varying degrees of dirtiness.

Dr. LAPP. If I may muddy the water a little more, I would say that one must also include here in this argument about clean and dirty bombs the operational aspects of the weapon. You have first the problem of how much dirt is actually produced by the bomb, and then you have second the problem of how much dirt comes down. If you test the bomb at high altitude and set it off at high altitude, then you minimize the local fallout.

So we have two problems here. To get an index of dirtiness of an actual weapon tested you have to apply some formula here for the eternal dirtiness, and then the operational dirtiness. So it is a complex thing.

Senator ANDERSON. Doctor, if you had developed a type of bomb that would not explode high in the atmosphere but equipped it to explode close to the ground, would you add or subtract from its dirtiness? Would you not add to its dirtiness, so-called, to get down where it picked up particles of soil?

Dr. LAPP. When you pick up, I would call it the ballast, the soil debris, it tends to maximize the local fallout and make the weapon dirtier.

Senator ANDERSON. Therefore, if we were to prove whether our interest was clean or dirty weapons, we would need testimony from the military as to whether they had or had not developed weapons that would explode closer to the ground.

Dr. LAPP. I believe that the operational aspects, namely, the altitude of detonation would be very important. The testimony that Dr. Shafer gave is illustrated on this chart in which the varying degrees of contamination are illustrated by different colors. I am not going to use the exact figures. I merely wanted to illustrate the type of continental contamination that you get into if you have an attack with 2,500 megatons of dirty bomb.

I would take an example and then discuss the implications of dirtiness in a strategic attack upon a country. If you assume that 50 percent of this dirtiness falls out locally, you have then 1,000 megatons

of fission products concentrated upon Northeastern United States, the region which I use, and much of the region would then be subject to a fallout of 10,000 eternity roentgens.

May I define that? The eternity roentgen is a unit of the exposure from one hour, considering that the time of fallout to deternity, it is divided up on the following time schedule. May I jump to section C, which is the persistence of fallout. May I bypass the comments about this and jump directly to the data.

If you have 10,000 eternity roentgens, this amounts to a rate of 2,000 roentgens per hour at one hour. Here is the time table of the delivery of the roentgens to a person exposed in the open on a flat area. From the first hour, assuming the fallout occurred, then, to the end of the first day, there would be 4,700 roentgens of exposure. That would be about 1C times the lethal dose for an individual. So he had better be somewhere besides the top of the earth.

From the end of the first day to the end of the first week, there would be a dose of 1,730 roentgens, or about 3 times the lethal dose. From the end of the first week to the end of the first month there would be an additional dose of 920 roentgens which would probably also be lethal. From the end of the first month to the end of the first year, there would be slightly over 1,000 roentgens. From the end of the first year to 50 years would be an additional 840 roentgens, but I make the note that weather and terrain would make a significant difference in cutting down that dose.

This point, I think, is worthy of stressing, because of its great implication for civil defense and for analyzing what the ultimate consequences of an attack upon a country are. You have the problem here of confronting 920 roentgens from the first week to the end of the first month after the attack, and even after that is over, you have the problem of the 11-month dose of slightly more than 1,000 roentgens. After the first year, there would be a smaller dose of some 840 roentgens that would be the theoretical maximum.

Having listened to Dr. Crow's testimony yesterday, I proceeded to calculate late last night or early this morning—I forget which—just what this would mean because Dr. Pollard and the others pointed out the consequences of an attack upon the United States, and Dr. Libby this morning emphasized the great consequence of a nuclear attack itself.

Representative HOLIFIELD. I am glad you are going into this, because the chairman has received any number of telegrams—in fact, 1 was delivered at 6 o'clock this morning when my doorbell was rung by a messenger, and they got me out of bed to give it to me—condemning the committee for not going into the effects of a war and possible multimegatons. Apparently the people writing in are not aware of all the testimony, and are not aware of the fact that the extrapolation from this information can be applied to multimegaton exposure of the population. So I am glad you are bringing that point out.

Dr. LAPP. I just had the opportunity of discussing this at lunch with Dr. Crow. I have some adjustments to make with it, but nonetheless in view of the nature which he will agree is fairly approximate data, I will let these figures stand.

What I did here was the following: I assumed that by some means we were extremely fortunate in having the attack. I mean we were

fortunate after the attack in being able to hide our people from acute dosage during the first month.

I went on to calculate how much dosage these people would get if we took a generalized smear out of the radioactive fallout over the continental United States. Here is where the eternity roentgen square mile is an extremely useful concept, because I can simply make the calculations very quickly.

What I did was to arrive at through this mathematics adjusting for weathering at an average dose of 400 roentgens for the average exposure to every American who survived an attack of 2,500 megatons, with some 2,000 megatons of fission products released.

Senator ANDERSON. Doctor, it is hard to translate these things back and forth. The other day when Dr. Russell was testifying, we got into the question of the fact that if a person was exposed to so many units, it might shorten the lives of children by a certain number of days and so forth. Are these roentgens what you have called eternity roentgens the same thing he was talking about?

Dr. LAPP. I have adjusted. I used the eternity roentgen just for the simplicity of calculation. I have gone back to the pure roentgen.

Senator ANDERSON. 400 roentgens would be a very substantial dose for not only the person exposed, but would have very, very substantial effects upon children that generation and continuing, as he pointed out, for several generations to come. Geneticists did not stop when the individual was exposed. They went right along through the several generations.

Do I understand that this is a sufficiently large dose so that it would shorten the lives of those children depending upon whether you used the upper or lower limits of Dr. Russell's table from 10, 15, or 20 years or something of that general nature, if the father and mother got 400 roentgens.

Dr. LAPP. I am not familiar with Dr. Russell's data. I am sorry.

Senator ANDERSON. Are these the same roentgens he was thinking about?

Dr. LAPP. They are the same roentgens. The roentgen is the roentgen and if he was talking about the roentgen, this is the same roentgen. If he was talking about the neutron unit, this would be different.

Representative COLE. Was he talking about the neutron unit?

Dr. LAPP. As I judge from what I heard in this hearing, I thought he was testifying about the neutron unit. Is Dr. Russell here?

Representative PRICE. He definitely stated he was talking about the neutron.

Dr. LAPP. You all saw Dr. Crow's table, I believe, showing the expected genetic effect upon the first generation and upon the total succeeding generations. What I did was to calculate how this would scale up if you had an aftermath of a nuclear war under this very optimistic condition that the people who survived got no radiation for the first month, but then were exposed to a cumulative dose of 400 roentgens over the period of a generation—a reproduction generation. The first generation, according to this table, would have 1,600,000 physical and mental defects, a total of 16 million for all total generations. There would be stillbirths and childhood deaths of 4 million, a total of 120 million for all generations. Embryonic and neonatal deaths, 8 million, and 140 million total, and a much larger but unknown number of intangible defects. (See p. 1021.)

I think I would have to change this on the basis of what Dr. Crow told me, instead of 2 out of every 10 children in the United States in the first generation would be genetically defective, it would have to be 1 out of every 10. The sum total of all deferred deaths from the attack would be 272 million. I believe that should be scaled down because of what he told me to somewhat less than that. I believe about 150 million. I will have to check with Dr. Crow on this.

This, then, is the kind of genetic consequence from an attack which, according to Dr. Shafer, would have produced, I believe, of the order of 80 million deaths.

This kind of a calculation is to me a rather awesome one. When I was thinking it over and talking with Dr. Crow at lunch, I was thinking, supposing this happened and you tried to imagine what you could do about it in advance. Of course, one of the things you could do is to arrange for shelter of people, but shelter of people for the time periods we have in mind is going to be increasingly difficult even if we have the funds for it. I hope I can be forgiven for injecting in the testimony at this time a thought which I had. It is the nature of nuclear warfare which provokes this. There perhaps might be a national objective to have a stockpile of human sperm—the male sperm—which would be stockpiled at strategic locations in the United States for providing at least on the masculine side a pure line of nonirradiated sperm. I realize that this may seem like a bizarre suggestion. I understand according to biologists that you can keep human sperm viable for considerable periods of time. If you did that, then I believe you would cut your genetic consequences more than in half, because I understand that the female is less sensitive to radiation than is the male in terms of the sperm versus the ovum. This means you could cut in half or less than half—you could probably cut down between a half and a third—the consequences to future generations. It may even be, and here we would have to do a great deal of research, if you could continue the integrity and viability of the sperm through more than one generation, you then could continue nonirradiated nonmutated sperm through more than one generation.

I realize here I am getting a little fanciful. I am merely injecting this into our discussion, the kind of things you come up against when you consider the awesome consequences of nuclear warfare.

Representative COLE. Dr. Lapp, you have, of course, posed a most intriguing and bizarre as well as fanciful suggestion, but it occurs to me that is it not likely that if such an event occurred in which such a large proportion of our population were affected to the point where it would be advisable or helpful if we could have a reservoir of sperm, would not that concentration also affect other animal and plant life to a degree in which even though we were able to reproduce the human race, we nevertheless could not survive because of insufficient food, water and such?

Dr. LAPP. Mr. Cole, I believe that so far as the crops reproducing themselves are concerned, this would not be the fundamental problem, because I believe the mutation rates are quite different in crops and some of the other animals. I would like the specific question of the relative biological effect genetically to be addressed to one of the geneticists.

Representative HOLIFIELD. Of course, the suggestion you have made is an unusual suggestion, but we are dealing now with a world in

which the possibility of releasing these quantities of megatons of fission are either here or will be here very soon. It just accents the gravity of nuclear warfare and this is, of course, one of the things which mankind has to deal with for survival of the human race. If we are going to have this kind of warfare, these are the problems that are presented.

Dr. LAPP. Mr. Holifield, I personally believe that projections of the probable consequences of a nuclear warfare are in themselves the greatest deterrent to war. But this has to be absorbed on both sides of the Iron Curtain. From what Dr. Muller said yesterday about the state of genetics in the Soviet Union, I think it might be quite advisable to make sure that no one in the Soviet Union is in doubt as to the consequences of a nuclear war.

I am at a loss to say how to do this, but it might be accomplished through a good conference on genetics to which the Russians were invited.

Representative COLE. Dr. Lapp, you have indicated that since your luncheon visit with Dr. Crow you have revised your conclusions from your original script which estimated an effect on the first generation of 2 out of every 10—since your luncheon visit with Dr. Crow you have revised that downward to 1 out of 10, which is a very striking revision, a difference of a hundred percent; if that can be the consequence of a luncheon visit with Dr. Crow, might it not be conceivable that if you spent a dinner evening with Dr. Russell and other scientists, you might further revise your figures one way or another, or if you spent a week with them there might be even a greater revision?

Dr. LAPP. I am not sure that the degree of revision would be proportional to the time of contact with these individuals.

Senator ANDERSON. You would find out that at one time the Atomic Energy Commission had a figure of 50 which in a short time they brought down to 2. Maybe they should go to dinner also.

Dr. LAPP. I apologize to the committee for introducing this figure, but I did not understand from Dr. Crow's testimony yesterday that these two figures he gave were not mutually exclusive.

Representative HOLIFIELD. Mutually what?

Dr. LAPP. The point was that in the column of data he presented, he had two figures, one of which actually enveloped the other. I had thought they were separate. I was in error.

Representative COLE. I was impressed by the apparent fact that a casual luncheon conversation could result in such a striking revision of your conclusions.

Dr. LAPP. The same factor of two would have been produced from a single sentence he gave me when I showed him the results. This is entirely in the nature of how scientists iron out these differences. They talk with one another.

Representative HOLIFIELD. I might say that we have had many statistics given to us that range all the way from a factor of 2 to a factor of 10 or 15. So this variability in your figure is not unusual to other testimony we have had.

Dr. LAPP. I believe in presenting the data Dr. Crow mentioned that it probably was not exact by a factor of three. I suspect it could be even more. I am merely using this as an indication. I would claim no precision.

Representative COLE. But his admission that his calculations might be in error by a factor of 3 was based upon long periods of sober study and concentrated thought, and that even after such long period of study, he came to certain conclusions which he admits might nevertheless be in error by a factor of 3.

You have indicated that your statement today was composed in the wee hours of last night and the early hours of this morning, as well as the luncheon visit. Therefore, might it not be reasonable to conclude that your estimates might be in error by a factor of as great as 15 or 20?

Dr. LAPP. I think the physical calculation I have made I would be willing to stand on. I think it is correct within the method that I have estimated the figures are accurate. The uncertainty comes in when I apply it to the genetic data. Actually, I think, Mr. Cole, I have underestimated the situation deliberately. I have taken lower values, not upper ones.

One of the most important things that I wanted to discuss at least in my opinion before this committee, and I hope I can jump to it is the problem of the present test rate. I have indicated in the last page of this testimony my rough estimate—and I emphasize that it is a rough estimate upon all the data available to me of the rate of testing, the injection of fission products into the stratosphere over the past period of time since the first bomb was exploded in 1945.

This is a semilogarithmic plot. That is, the scale on the left in logarithmic. Starting at the bottom, the lowest value given in one megaton, and it runs up to 10 and 100 megatons of fission products injected into the stratosphere. To be perhaps redundant, may I explain that this is the number of fission products associated with the explosion of 100 million tons of TNT equivalent fission energy in a bomb. The reason why nothing appears up in 1951, up to the small value which I indicated as two-tenths of a megaton, is that prior to that time we were in the fission domain of weapons—the pure fission domain of weapons—in which the weapons had their energy released by a chain reaction in fairly expensive uranium 235 or plutonium 239, material which, as a rough estimate, we can say cost $10,000 a pound. The price is somewhat less now. Up until that time we were dealing with relatively small weapons and because of the fact that these weapons did not have great explosive power as compared with the megaton class weapons, their fission debris was restricted to the lower atmosphere or to the troposphere.

This meant that so far as the global aspects of radioactive contamination were concerned, and considering the method of transportation, the total amount of fission debris deposited was small and negligible. It was only when we entered into the era of the megaton in weaponry that we started to get into a situation where the injection of radioactive fission products into the stratosphere because of consequence and could be measured remotely all over the world.

If we look at that, we will find in the injection corresponding to the test in 1952—by the way, this includes the United States and U. S. S. R. I have not included any contribution from the British—and in 1953, relatively little testing so the curve goes down. In 1954 was when we had the Castle series of tests with a total estimated contributed fission yield of 30 megatons into the stratosphere.

The next year was cut back to a total of 3 megatons and then the next year, 1956, it went up. If you will permit me to go to another curve, I can give you the estimate. It is to about 14 megatons. I am not in a position to make an estimate of the 1957 contributions since I am not aware of what the British have contributed with the Christmas Island test, and am only partially informed of what the Russians have contributed with their spring series of tests. But I believe that this chart does illustrate some of the problems you have in discussing the present rate of testing.

One way—and this is the way Dr. Langham suggested—is that you simply average the testing over the past 5 years, which would mean we take these 5 bar graphs and add them up and divide by 5.

I believe that when this is done that this curve will come out to somewhat more than Dr. Langham estimated. I am not sure that in just a minute I can give you the answers to that.

Senator ANDERSON. Very close to it.

Dr. LAPP. It is close to it.

Representative HOLIFIELD. Of course, this excludes the Russian test.

Dr. LAPP. This includes the Russian test. I have been conservative with regard to the Russian test, probably overly conservative, because of the problem of estimating just what fission yield they had in the weapons, how much was injected into the atmosphere, and how much dumped out stratospherically.

Senator ANDERSON. Dr. Langham said it came to about 50 megatons in the past 5 years. If you add your figures, it comes out to about 50 and a fifth of that is 10 megatons per year.

Dr. LAPP. It is roughly 50, sir. I do not have the complete detail here as to how I arrived at all these figures. The reason for the Castle series of test figures being there is due to Dr. Libby. He presented the data which allows me to derive this value for the Castle series of tests. That is the principal contributor, and thus explains why my estimate should be so close to Dr. Langham's.

There is one thing which has puzzled me, that is, that if these data are in fact correct, then the Russians have not really tested a series comparable to our Castle series of tests.

Senator ANDERSON. It could be that we had one fairly sizable shot that has not yet been approximated by anybody else. That is a possible explanation.

Dr. LAPP. That is possible. I can only draw an inference.

Senator ANDERSON. Would you not be satisfied to take the total figure that Dr. Langham used in view of the fact that he is so closely associated with Los Alamos Laboratory which for many years of this period was doing the major part of the testing and has since been joined by Livermore—but the two laboratories work very closely together and their scientists are certainly knowledgeable of everything that has taken place in the tests thus far—they have the translations of what the Russian tests have been insofar as we are able to detect them, and could you not agree with him that 50 megatons would be about the total for 5 years and 10 for each year?

Dr. LAPP. I believe the agreement is very close, and I would certainly go along with Dr. Langham. The range of estimates for the test limit for the injection of radioactive material, assuming equilibrium, runs in the range of from 2 to 10 megatons, according to the discussion before this committee at the round table of Dr. Neuman and Dr.

Langham, Dr. Eisenbud, Dr. Kulp and one other person whom I have forgotten.

Because of the way I have made estimates before, I have used a value of 3 megatons per year, with a factor of 3 either way. In other words, it might be as low as 1 megaton per year or it might be as high as 9 megatons per year. One can see from this that our own test rate has exceeded this value. If we take three, it is exceeded about twice. If we take 10, it has exceeded once plus the Russian contribution, which would be a global passing limit of 2 times in the past decade.

This is assuming equilibrium. You are going to have to have more tests before you will load up the stratosphere. So from the standpoint of being reckless, the United States has not yet exceeded the limit.

I would like to make that very clear. I do not think my written statement adequately brings that out.

I realize I am taking a great deal of the committee's time, and I would like to go through some of my testimony relatively quickly. Perhaps the question of the future nuclear tests should be discussed briefly. I think in dealing with future commitments of radioactive debris to the earth's atmosphere we must deal with many unknowns. Had we attempted an estimate 5 years ago prior to Castle-like weapons we would have arrived at most misleading and optimistic projections. The end of weapon development is not in sight, and no one can say that unexpected developments may not occur. For example, may not smaller nations be stimulated by British success with thermonuclear type weapons and place maximum emphasis upon such development?

Additionally, can we be sure that a nation would restrain itself and not test a 100 megaton dirty weapon if military requirements and nuclear technology indicated that such a weapon was desirable in its own security interests.

Will not the requirements of adapting maximum megatonnage to a small warhead put emphasis on further development of dirty weapons?

I cannot answer these questions at this time, but I know that single weapons tests of very high fission yields can add a strontium burden to the atmosphere far beyond the limits we have been discussing here.

The United States has contributed the largest fraction of the radio strontium to the stratosphere, and I think it is distinctly encouraging that the fullest discussion of the strontium fallout should occur in this country. I am not aware of any large body of published information on this subject of Soviet origin. It is known, however, that the Soviets are engaged in strontium studies.

In concluding this section, I would again like to stress Dr. Libby's contributions to this subject. They are of very great value and I feel sure that we would be in a much poorer position today to evaluate the strontium problem were it not for Dr. Libby's personal interest in this field of investigation and the research which he has pushed so vigorously.

On the strontium problem itself, I would like to state briefly strontium 90 determinations in man must be expanded to assess the increase in strontium 90 burden which will occur in future time. Careful determinations of natural strontium in humans deserve increased

attention. We know that more strontium 90 will accumulate in humans as a result of bombs tested in the past and as a result of current tests. I believe that Dr. Selove is going to give a further discussion of this. The determinations as to how much of the radio element may be tolerated safely is a matter for the biologists to discuss.

This committee has heard a fairly wide range of opinion from its expert witnesses on the probable biological effects of strontium 90 in man. But it seems to me that even in this area some agreement was reached, especially when Dr. Shields Warren stated on June 3:

> I would be reluctant to see the average strontium 90 content of bones, particularly in children, go much above 10 times the present level.

Dr. Libby's speeches show that the strontium 90 fallout will continue, and the strontium 90 level in human bones will increase.

I believe that unless restraints are imposed upon commitments of fission products to the atmosphere, it is only a matter of time before the strontium 90 level of Dr. Warren will be reached.

I would not be able to extrapolate that curve very well into the future to determine this.

I would like to jump to constructive proposals—at least I believe they are constructive—if I may just insert one comment here.

A colleague, Dr. Jack Shubert, who is presently at the Laboratory for Inorganic Chemistry in Zurich, Switzerland, from the Argonne National Laboratory, and he has been in Britain recently and discussed data with the British on the question of the relative sensitivity, I would like to quote from a letter I received last night from Dr. Shubert:

> It used to be thought that at least 1,000 roentgens of absorbed radiation would induce cancer. Within the past few years, it has been found that as little as 200 roentgens delivered to children would induce cancer in later life. Now it has been found (this is by the British) that as little as 3 to 5 roentgens received by the unborn child in its last 2 months before birth has been responsible for cancer of all types appearing a few years later.

I believe that this statement from Dr. Shubert which represents the final conclusions of the data of Dr. Alice Stuart in England, is significant in that it does show that the incidence of cancer malignancy in children correlates with the X-ray of women prior to term. This is diagnostic use of X-rays which in the case of X-rays may involve of the order of a few roentgens, an amount which was thought harmless.

I believe also that this would have significant bearing upon the question of the threshold.

In order to allow time for my friend, Dr. Selove, may I jump quickly to my proposals and read them for you.

A. ATOMIC ENERGY COMMISSION INFORMATION POLICY

I suggest that this committee or its parent committee may wish to review the information policy of the Atomic Energy Commission, and I might add the Defense Department, with regard to nuclear weapon effects, with a view toward revising this policy so that information may be made available more promptly and completely. I am thinking particularly of the relations of the Atomic Energy Commission with the press. I believe that the national interest de-

mands a better relation, a freer flow of communication between the Atomic Energy Commission and the press.

My second proposal, I suggest that the Joint Committee on Atomic Energy might wish to recommend or to sponsor the preparation of an analysis of the probable biological effect of nuclear warfare. It would be useful to investigate probable lashback effects from various levels of nuclear bombardment. What I am thinking of under this category of lashback is the fallout which would occur upon the country which uses the nuclear weapon itself. That would be the remote tropospheric fallout.

The third point, data useful to civil defense. I believe that the committee's investigations have produced information of critical value to the civil defense planning. It might be useful to have a summary report of these data transmitted to the FCDA. I say that because I personally have not seen many representatives of the FCDA at these hearings.

Research in long-range estimation of nuclear explosives. It is known that considerable effort has focused on long-range detection of nuclear detonations. Attention should be given to the declassification of such data as would bear upon evaluation of the radio strontium problem. In particular I have in mind helping us to estimate how much the Russians are contributing, if this can be done, without jeopardizing sensitive data. Other data would be most useful in discussion of the feasibility of policing an agreed upon test limit, if one could get a multilateral agreement.

Annual fallout report. In view of the great public concern over fallout hazards, I would urge that the Atomic Energy Commission be required to issue an annual report on the degree of fallout and its uptake in biological systems. Perhaps the Atomic Energy Commission might wish to have that report prepared by a university task force.

Finally, I would urge that the Congress continue its investigations of radiation hazards, extending them into the broader area of peacetime uses of radiation. I believe that the ever-increasing uses of radiation must be subject to legislative controls. Radiation protection in the United States needs, in my opinion, uniform legal status.

Representative HOLIFIELD. Thank you very much, Dr. Lapp. Unless there are questions, we will hurry on to our next witness, Dr. Selove, in order that we might finish with him in time for the conference.

Representative COLE. Mr. Chairman, I should like to ask a few questions of Dr. Lapp, in order only to clear up what appears to be a conflict or some discrepancy in statements with respect to his experience and connection with the atomic energy program.

Dr. Lapp, have you seen the biography of yourself which has been prepared by the Joint Committee?

Dr. LAPP. I am sorry, I did not.

Representative COLE. I wish you would look at it if you would to see if that is a correct representation of your activities in the field of atomic energy.

Representative HOLIFIELD. I understand that the staff took that from the American Men of Science compilation.

Dr. LAPP. I believe it is correct from cursory examination.

Representative COLE. I would call your attention particularly to that part of the biography which states that you were Deputy Execu-

tive Director of the Atomic Energy Commission Joint Research and Development Board during 1947–48, and Executive Director during 1948–49. The information which has been given to me from reliable sources is the fact that you have never been an employee of the Atomic Energy Commission.

Dr. LAPP. That is correct.

Representative COLE. That is why I am giving you an opportunity to clarify this apparent discrepancy.

Dr. LAPP. May I read what it says here? It says, "Deputy Executive Director, Atomic Energy" and then there is an unusual abbreviation "Cmm Atomic Energy Committee of the Joint Research and Development Board," which was part of the Defense Department. It was Vannevar Bush's show. I am happy you brought this up. Frequently (I give lectures) I am introduced in a way which is embarrassing to me because it is incorrect. I have been introduced as everybody from the Chairman of the Atomic Energy Commission on down the line. This statement actually is correct, if you understand that is committee and not commission.

Representative COLE. How can you possibly get committee out of "Cmm"?

Dr. LAPP. I am not responsible for this. I am sorry.

Representative COLE. Then at any rate it is a fact that you have never been an employee of the Atomic Energy Commission or a consultant to the Commission.

Dr. LAPP. That is correct, Mr. Cole, I have never represented myself as such.

Representative COLE. I am not saying that you did. I am simply trying to give you an opportunity to clarify the facts of your experience in this field.

Dr. LAPP. I am glad to have this opportunity to state on this record that is correct.

Representative COLE. I further call your attention to the item "Head, Nuclear Physics Branch, Office of Naval Research, Department of Navy, 1949–52."

Dr. LAPP. That is incorrect.

Representative COLE. That is incorrect?

Dr. LAPP. That is incorrect.

Representative COLE. What is the fact?

Dr. LAPP. It was Acting Head, Nuclear Physics Branch, Office of Naval Research, Department of the Navy, 1949.

Representative COLE. 1949?

Dr. LAPP. I am sorry. Again I am not responsible for that.

Representative COLE. It is the fact that in 1949 you resigned from that post with the Office of Naval Research.

Dr. LAPP. That is correct.

Representative COLE. I do not press you on it, but would you care to give your reasons for your resignations?

Dr. LAPP. I stated on the record that I resigned of my own volition at that time.

Representative COLE. I am sure you did of your own volition. Were there peculiar circumstances surrounding the resignation?

Dr. LAPP. I had taken the job with the Atomic Energy Commission—pardon me, you have me mixed up—at the invitation of Dr. Widdel as a temporary appointment while he slid out from the posi-

tion of Head of the Nuclear Physics at that time. I took it for a short time and then resigned, I think, in June of 1949, Mr. Cole.

Representative COLE. Then there were no unusual circumstances that prompted your resignation?

Dr. LAPP. I think I would have taken this job only for a short time. I was lecturing or beginning to lecture. I was finding it difficult to lecture and also be employed by the Defense Department. But the job was temporary.

Representative COLE. That is all I have, Mr. Chairman.

Dr. LAPP. May I read the rest of this to make sure there are no other corrections? I believe it is correct as it stands now, as corrected.

Representative VAN ZANDT. Mr. Chairman, there still is in the record this statement attributed to Dr. Lapp, "reckless or nonsubstantiated statements do a disservice to the AEC and to the Nation." This statement was directed at Dr. Eisenbud, Dr. Libby and Dr. Doan. I would like to ask the Chair if we are going to give these three distinguished Americans an opportunity to answer the accusation?

Representative HOLIFIELD. Yes, sir. Would the committee like to have them come forward at this time or would you like to go forward with the next witness and have that take place in the conference?

Representative COLE. Mr. Chairman, if we are through with Dr. Lapp, I would strongly urge that we invite Dr. Eisenbud, who is in the audience, to come immediately to respond to Dr. Lapp's charge.

Senator HICKENLOOPER. Mr. Chairman, I would suggest that we finish with Dr. Lapp first. I have some questions I would like to ask.

Representative HOLIFIELD. Senator Hickenlooper has some questions, Dr. Lapp.

Senator HICKENLOOPER. Dr. Lapp, have you ever done what might be called extensive works in genetics under your own responsibility in connection with the effects of radioactivity on human cells?

Dr. LAPP. No, sir.

Senator HICKENLOOPER. Have you ever done any research in biology and medicine in connection with the effect of radioactivity on the genes or other parts of the human body?

Dr. LAPP. I have never done any research on genetic effects.

Senator HICKENLOOPER. Have you ever conducted any research yourself on the fallout or its intensity in this country? By that I mean any laboratory research of any extent.

Dr. LAPP. I have made some simple measurements myself, but my data here and my testimony is based upon the data of the Atomic Energy Commission.

Senator HICKENLOOPER. That was the next suggestion that I wanted to make. I have the impression here—I do not know whether I am correct or not—that you are appearing here more in the nature of a reporter or a correlator with some considerable educational background, I admit, of the scientific data as you personally interpret it, which has been compiled by a number of eminent scientific people who have actually done the work.

Dr. LAPP. I believe the invitation that was extended to me by the committee more or less put me on these lines of testimony.

Senator HICKENLOOPER. Yes. The only purpose of this suggestion is that you are not here, while you are a scientist in your own right on your education, giving firsthand evidence based upon data with which you have been acutely or intimately connected in connection with its

development. So you are reporting what you have read or what you have been told by others with varying degrees of accuracy and drawing your own conclusions.

Dr. LAPP. Mr. Hickenlooper, I think it is a fair statement to say that I have done considerable work based upon information made available by the Atomic Energy Commission and scientists in general. I have done active work in gathering data from people, especially as every scientist will do, when available.

Senator HICKENLOOPER. I know that. I make the point that there are several very eminent newspaper reporters in the scientific field who have also done a tremendous amount of work of gathering data and yet they have done no research of their own. They are reporters and in a very proper field they are reporting what they find. I merely have the impression that you are here today in the nature of a reporter or a compiler of information which you are interpreting as you see it. As differentiated, I might add, from the testimony of most of the rest or all of the rest, perhaps, of the witnesses we have had here who have been intimately working in this field and present the results in the main on their own experience, and the results of their own work.

Dr. LAPP. I believe, Mr. Hickenlooper, this is within the framework of the outline which requested me to testify.

Representative HOLIFIELD. I am very sorry. In order to correct the record, the Chair will have to state that Dr. Libby is a chemist, and the information he has given us in every field of science has been obtained from his association with other scientists and reading of other materials. So in order to keep the record straight, let us have the facts spread there that it is not only Dr. Lapp who had studied the other scientists' work and reported on them, but also Dr. Libby, one of the AEC Commissioners.

Dr. LAPP. May I say in general response, not specifically to Mr. Hickenlooper, that I admit to being critical of the Atomic Energy Commission. My criticisms of the Atomic Energy Commission, I always felt, have been directed toward trying to bring the facts out into the open, and the free play of public discussion. As Dr. Libby testified this morning, some of the problems involved here transcend the area of science. I have felt that this is important. I have tried to help in the somewhat new but I think important problem of education in science.

Senator HICKENLOOPER. Then where do you obtain your facts? Do you have access to restricted data?

Dr. LAPP. I have no access to restricted data, Mr. Hickenlooper. The facts that I have presented here are based upon information which is available freely in the scientific domain.

Senator HICKENLOOPER. Not only in the scientific domain, but from the Atomic Energy Commission also. Is that not true?

Dr. LAPP. Such data as the Atomic Energy Commission published. We were assured this morning by Dr. Libby that all of the data except for a very small fraction dealing with a long-range detection on Project Sunshine had been put in the public domain.

Senator HICKENLOOPER. What information do you have that the Atomic Energy Commission is not making available, if you have no access to restricted data, and if your information comes from data freely available from various sources including the Commission? Does not that indicate that data is being made available?

Dr. LAPP. If I may respond to the question, Senator Hickenlooper, my complaints in the past about the slowness with which the Atomic Energy Commission emitted data, which I thought were vital to civil defense, were, for example, that the data were not available. They had to be derived by me from other sources, other than the Atomic Energy Commission. As for example, the scientific data from Japan. Thus I think the fact that later on the Atomic Energy Commission actually confirmed through its pronouncements that these results were correct testified——

Senator HICKENLOOPER. Have you had an opportunity to go through the data in minute detail from Japan, examine the records and all the data that they have developed, or are you relying entirely upon the verbal statements of certain scientists made to you in the course of your visits with them?

Dr. LAPP. No. I have been in communication with Japanese scientists for some time. I have received letters and photostats and copies of their scientific papers, in some cases prior to publication.

Senator HICKENLOOPER. Thank you very much.

Representative COLE. Mr. Chairman, I had intended to interrogate Dr. Lapp just a little bit about his visit to Japan earlier when he referred to his visit in his statement. While I hate to keep him on the stand unduly, I am curious to have his observations on two points.

One is, Dr. Lapp, that you were registered as one of the scientists who would attend the conference.

Dr. LAPP. Yes.

Representative COLE. And yet you did not attend the conference.

Dr. LAPP. No; I did attend, Mr. Cole.

Representative COLE. It was reported to me, and the reason I raise the question is because that same question was raised by a number of persons who were there, as to the reason why you had not attended the conference.

Dr. LAPP. I would be glad to explain this.

Representative COLE. That is one point. Then the other, since you remained in Japan after the conference was concluded, I am interested to have your observations with respect to the accomplishments of the conference.

Dr. LAPP. On the first point, I arrived in Japan on, I believe, May 1, considerably in advance of the conference. It was my firm intention to attend every session of the conference, because I am very much interested in the work of the Atomic Industrial Conference. However, when I got to Japan, I found myself in a pretty mad race because I was digging up some data on the *Lucky Dragon* story, interviewing some of the fishermen who were in this unlucky boat; and I wanted to visit Hiroshima and visit some scientists in the various places. I found that when I had to deal with just the problem of hours spent in talking with the fishermen that by the time I got back to Japan the conference had already started. This was unavoidable, but I had to meet people at certain places.

Then the amount of commitments I had with the press and visiting the *Lucky Dragon* itself precluded my going to more than one session.

Representative COLE. Which session was that? It does not matter.

Dr. LAPP. I can give it to you. I did attend that. I wanted very much to attend the luncheon and dinner sessions. I had all the tickets, and I just could not use them. For example, the one night I wanted

to do that, I think I was invited to a banquet by one of the prominent newsmen. So I, unfortunately, did not have much time.

As for the second point, just what was my reaction, I did not have too much opportunity to discuss with the Japanese scientists their reaction to the conference, but I gathered from conversation with a few of them that they were greatly impressed with the conference. It was very well managed. It was well attended. I think they were very much impressed with the general conference.

Representative COLE. Then your conclusion is that it was a very worthwhile conference.

Dr. LAPP. I would say so.

Representative COLE. That is my own conclusion.

Dr. LAPP. Yes.

Representative COLE. I can also verify your statement that it was an extremely well-organized conference involving a considerable number of people. There were some meetings that were attended by as many as 4,000, 5,000 and 6,000 Japanese. It was an unusually well-organized conference, probably the first international conference of industrialists and scientists that has ever been held.

Dr. LAPP. I would in no way like to detract from the value of this conference. My only regret is that I was able to attend so few sessions. I cut short my visit in order to come back here. I would have liked to stay in Japan much longer.

Representative COLE. My only basis for concluding that you had not attended the sessions of the conference is that I inquired—because I looked forward to seeing you there—inquired at the registration desk at the end of the conference, and they said you had not, so far as they knew, attended the conference, and the papers in the box—there was a slot for each of the delegates—were still there.

Dr. LAPP. I have the papers in my office, Mr. Cole. Again I regret, and no one does more than I, that I could not attend these conferences. I was working. The press in Japan can at times be very aggressive. Perhaps you found that out yourself.

Representative COLE. Yes.

Dr. LAPP. I found myself going to a 15-minute interview and ending up with a 2-hour luncheon.

Representative COLE. Now, with respect to your sources of information, Dr. Lapp, you have indicated that your observations back through the years are based on reports and studies of unclassified data that have come to your attention. Are they not, also based on discussions with other newspapermen and analysts in this field, such as yourself?

Dr. LAPP. I am proud to say that I communicate with a great many members of the press.

Representative HOLIFIELD. Mr. Eisenbud, you are now given an opportunity to reply to the comment of your colleague in science, Dr. Lapp.

Senator ANDERSON. Before you do so, Mr. Eisenbud, may we sort of follow along in this same pattern of qualification? I look at your qualifications in here, and I see "EE, New York University." Does that mean "electrical engineer"?

Mr. EISENBUD. Yes.

Senator ANDERSON. What subsequent degrees have you acquired?

Mr. EISENBUD. I have no subsequent degrees.

Senator ANDERSON. Just the degree as electrical engineer?

Mr. EISENBUD. Many years ago; yes, sir.

Senator ANDERSON. I see you spent more time working for the Liberty Mutual Insurance Co. as a hygienist than anything you have done in your life and more than all the rest of your experience put together; is that right? Eleven years with them, and only 10 years since then.

Mr. EISENBUD. That is about right.

Senator ANDERSON. I am not trying to be critical, because I tried to speak appreciatively of what you had done a few moments ago. As a hygienist, did you ever have occasion to get into the question of deposit of strontium 90 in the atmosphere for the Liberty Mutual Insurance Co.?

Mr. EISENBUD. This was previous to 1947. Up until that time very little strontium 90 had been formed in this world. The radiaition problems of those days were X-ray and radium. We were only beginning to get interested in the kinds of things which we are talking about today.

Senator ANDERSON. The field that you were in had to do with the detailed discussion of the occurrence of strontium 90 and cesium 137 in the atmosphere, biosphere, and its uptake and behavior in man. What was there in your electrical engineering course that dealt with that?

Mr. EISENBUD. Very little, sir. But a great deal in some 21 years of professional experience, during which time I have attained the rank of adjunct professor of industrial medicine at New York University Medical School.

Senator ANDERSON. What was there in this work with the Liberty Mutual Insurance Co. as a hygienist that started you off lecturing on medicine?

Mr. EISENBUD. I got interested, about 22 years ago, in a legitimate subject for a young electrical engineer, namely, the electrical charges on dust, and went from there to the general physical properties of dust, and then into the physiology of dust and dust diseases, and spent a great deal of time from 1936 until 1947 studying the general behavior of dust, not only in the atmosphere, but in the lung and in the body.

Senator ANDERSON. Your paper was headed, "A Measurement of Strontium 90 in Geophysical and Biological Material." Are you a geophysicist?

Mr. EISENBUD. Sir, I do not know, really, how to answer that. I think anybody that has some interest or qualification in geography and geology and some in physics could at least write on the subject of geophysics, but I am not a geophysicist.

Senator ANDERSON. Are you a biological worker.

Mr. EISENBUD. I work in the biological field. I, myself, am not a biologist.

Senator ANDERSON. Have you conducted experiments in this measurement of strontium 90?

Mr. EISENBUD. I have directed the experiments, and have conducted some myself.

Senator ANDERSON. Have you conducted them? Have you done any experimental work yourself?

Mr. EISENBUD. The experimental work was performed under my immediate supervision. I have done some of the experimental work myself.

Senator ANDERSON. Most of it was done under your supervision?

Mr. EISENBUD. This has been a large program. This is much too large for one man. It was done by my immediate staff.

Senator ANDERSON. Then you are here as a reporter of what someone else has done.

(A letter from Merrill Eisenbud, setting forth a full record of his qualifications, follows:)

UNITED STATES ATOMIC ENERGY COMMISSION,
NEW YORK OPERATIONS OFFICE,
New York, N. Y., July 12, 1957.

Mr. HAL HOLLISTER,
Staff Member, Joint Committee on Atomic Energy,
Congress of the United States, Washington, D. C.

DEAR HAL: You will undoubtedly recall that during the proceedings of June 5, the question of my professional qualifications was raised by Senator Anderson. If this portion of the testimony is to be included in the published proceedings, it would be desirable, for the sake of completeness, that a full record of my qualifications be included as well. The attached curriculum vitae is somewhat more complete than the record to which Senator Anderson referred and which I believe was the Men of Science abstract.

I am also attaching a list of my publications. I do not wish that this list be included in the proceedings but I simply submit it as a matter of record for the files of the subcommittee.

I continue to hear favorable reports about the hearings. We all look forward to the final proceedings.

With best regards.

Sincerely,

MERRIL EISENBUD, *Manager.*

BIOGRAPHICAL DATA, MERRIL EISENBUD, JUNE 10, 1957

Date of birth: March 18, 1915, New York City

Education: New York University, College of Engineering (1932-36) B. S. in E. E. 1936

Positions held:

- Industrial hygienist, Liberty Mutual Insurance Co., 1936-47
- Chief, Industrial Hygiene Branch, Health and Safety Laboratory, United States Atomic Energy Commission, 1947-49
- Director, Health and Safety Laboratory, United States Atomic Energy Commission, 1949 to present
- Manager, New York Operations Office, United States Atomic Energy Commission, 1954 to present
- Senior scientific advisor, Preparatory Commission of the International Atomic Energy Agency, 1957

Lecturer, Columbia, School of Public Health, 1945-50

Adjunct associate professor, department of sanitary engineering, New York University, 1945-50

Associate professor, industrial medicine, New York University, department of industrial medicine, 1950-55

Adjunct professor, industrial medicine, Postgraduate School of Medicine, New York University, 1955-

Committees:

- National Research Council:
  - Toxicology Committee, 1952-
  - Committee on Atmospheric and Industrial Hygiene, 1952-
- American Standards Association:
  - Subcommittee on Radium, Dust, and Radon Gas, Z37, 1949-
  - Sectional Committee on the Use of X-Rays, Z-54, 1951-
- National Safety Council: Executive committee, Chemical Section, 1951-
- Radiological Advisory Committee: Office of Civil Defense, City of New York, 1950-
- Technical advisor, United States delegation, U. N. Conference on the Peaceful Uses of Atomic Energy, Geneva, 1955
- Alternate United States representative, U. N., Scientific Committee on the Effects of Atomic Radiation, 1956-.

Member, National Academy of Sciences Committee on the Meteorological Aspects of the Effecvts of Atomic Radiation 1956–.
Aspects of the Effects of Atomic Radiation, 1956–.
Scientific adviser, United States delegation, Conference on the Statute of the International Atomic Energy Agency, 1956–.
Member, World Health Organization, Expert Advisory Panel on Radiation, 1957–.

Memberships:
American Industrial Hygiene Association (board of directors, 1955–58), American Public Health Association, New York Academy of Science, Radiation Research Society, American Association for the Advancement of Science.

LIST OF PUBLISHED WORK OF MERRIL EISENBUD

Global Distribution of Strontium-90 from Nuclear Detonations, Scientific Monthly (May 1957), pp. 237–244.
Monitoring Network for Measuring Radioactive Fallout, J. Am. Water Works Association, Vol. 48, No. 6 (June 1956).
Radioactive Fallout Through September 1955, Science, Vol. 124, No. 3215, p. 251 (August 10, 1956) (with J. H. Harley).

The Principal Health Hazards in Metal Finishing Departments and Their Control, Metal Finishing (1942).

Mr. EISENBUD. Thank you.

I am deeply gratified, Mr. Chairman, at the opportunity to correct the record with respect to the item which Dr. Lapp has included on page 2, paragraph C, in which he quotes a New York newspaper sentence and illustrates what, I think, needs not be illustrated; namely, the danger of taking something out of context. The date of that quotation is March 20, 1955. This was a very jittery period. This was immediately following the announcement within the AEC of the results of the March 1, 1954 detonation in the Pacific. It also coincided with the beginning of the Teapot series of detonations in Nevada, which, if my recollection is correct, began a week or two prior to this announcement, or perhaps shortly thereafter.

In any case, the fact that the first post-Castle detonations were about to take place in Nevada was very much in the minds of many of our citizens.

This reporter came to me to find out whether, in my opinion, the kind of accident which occurred in Bikini in 1954 could happen in this country as a result of the test being contemplated or already underway in Nevada. We were not talking about the long-range hazards of fallout. We were not talking about strontium 90. We were talking about the kinds of acute effects which one had, unfortunately, seen in both the Marshallese and Japanese fishermen in 1954.

My comment, which may or may not have been quoted accurately—I really don't know—had to do, primarily, with the relationship of acute effects to the kinds of radiation levels that are expected from the Nevada test, which are of the order of 1 milliroentgen or thereabouts, at least, in the United States.

Senator ANDERSON. Mr. Eisenbud, this statement was made on March 20, 1955. I understand you do not question the accuracy of the quotation.

Mr. EISENBUD. I do not question the accuracy of the quotation nor will I certify it nor will I certify the accuracy of Dr. Lapp's quotation of a quotation.

Senator ANDERSON. If it should prove he is accurate you are willing to stand by it.

Mr. EISENBUD. I am willing to accept this version of it.

Senator ANDERSON. The testimony introduced by Dr. Lapp and the chart introduced showed that we had the Castle series in 1954 in which we had put in the atmosphere more fission products perhaps in that year than we have put in all the rest of the tests together. Therefore we were at our highest peak when you made your comment. The figure was several times above the figure which Dr. Langham has said is a safe figure year by year.

It is your testimony that we could do a million times that and do no damage.

Mr. EISENBUD. No, sir. This was not the question which was asked of me. I was asked specifically whether there was any possibility in the eastern United States of an accident which would produce the

kinds of illness among the people that were seen in the Marshallese and Japanese fishermen.

This would require around 100 roentgen. The radiation doses which had been observed were something less than a milliroentgen. This is a ratio of about a million to one. When you put it into context it is perfectly accurate.

Senator ANDERSON. That is what I am trying to get to. We had just finished the Castle series. You would agree with that; would you not?

Mr. EISENBUD. That was a year before.

Senator ANDERSON. We had finished them in 1954 and this statement was made March 20, 1955. We had finished the Castle series, had we not?

Mr. EISENBUD. Yes, sir.

Senator ANDERSON. You said the total fallout to date from all tests would have to be multiplied by a million to produce visible deleterious effects except in areas close to the explosion itself. It is your testimony that having put that year into the stratosphere, or whatever fallout pattern there was, something in the neighborhood of 30 megatons of fissionable products, that we would have to put a million times that for it to have any ill effect except in the immediate vicinity of the test. Is that correct?

Mr. EISENBUD. That is incorrect.

Senator ANDERSON. You think that is a somewhat reckless statement?

Mr. EISENBUD. This is not what I said.

Senator ANDERSON. That is what I am trying to get to. The paper misquoted you.

Mr. EISENBUD. No, sir. I have not seen that quotation in 2 years. This sentence is out of context.

Senator ANDERSON. I am reading it to you. If it should prove to be an exact quotation, is it a reckless statement?

Mr. EISENBUD. Out of context; no.

Senator ANDERSON. In or out of context, is it a reckless statement to say that the Castle test which included an extremely large shot which turned loose in one series of tests as much fission products as probably all the rest of the tests by all the rest of the countries? If you can place reliance on the data gathered at Los Alamos, do I understand in context or out of context, you could have a million times that and have no visible deleterious effects except in the immediate area? Do you wonder that looking at that statement Dr. Lapp thought it might be a slight degree of recklessness?

Mr. EISENBUD. Sir, I would like Dr. Lapp to comment on what I have——

Senator ANDERSON. The point is that they wanted to give you an opportunity, and this is your day.

Mr. EISENBUD. Yes, sir. I think Dr. Lapp will probably understand what I am talking about. Let me say this, sir: I think it is a great misfortune——

Senator ANDERSON. Dr. Lapp was treated critically because he had used this language. They said in all fairness you would have an opportunity to reply. This is your hour for fairness. Why don't you go ahead and reply?

Representative COLE. I think he would if you let him.

Mr. EISENBUD. I think it is a great misfortune, sir, that to add to public confusion we find it necessary to discuss in the same session the long-range hazard and the close in hazard. For most of these sessions we have been talking about the long-range hazard from strontium 90 and from the gamma radiation.

In this interview I was talking about the close-range hazard, the kind of hazard that may develop within a few hours after detonation and the kind of hazard which produced illness in the Marshallese and Japanese in 1954.

Senator ANDERSON. Then from the close-range hazard—we will just confine it to that—since we put some 30 megatons of fission products in the atmosphere in the Castle test just passed, you believe that we could safely put a million times that in a single year in a test without doing any damage?

Mr. EISENBUD. Certainly not, sir.

Senator ANDERSON. What were you talking about? If it is not from the close range or long range, what other range is there?

Mr. EISENBUD. I was talking about the immediate gamma radiation from the fallout which occurs in the eastern United States within a matter of a day or so after a detonation in Nevada. This is not in the statement because the statement has been taken out of context.

Senator ANDERSON. Could that have been apparent if Dr. Lapp had read the whole interview?

Mr. EISENBUD. I can't vouch for the validity of the interview, sir. I do not recall this.

Dr. LAPP. I would like to make this statement in all fairness to Dr. Eisenbud, and I certainly do not mean to attack his integrity. The reason for quoting these and the use of the word "reckless" was to demonstrate the need for being quite exact when dealing with such a touchy subject as radioactivity. I am trying to interpret this recklessness not in terms of Dr. Eisenbud's personal recklessness but in terms of how it may appear to people who read these things and who do read single sentences.

Senator ANDERSON. I quite agree with you. I tried to say earlier that I think Mr. Eisenbud is a very fine public servant. I went up to him and told him that I appreciated very much the testimony he gave the other day. I did not regard your statement about him as a vicious attack upon him. But if it comes down to whether it was reckless, there are people who read that statement alone who would think it had just a slight tinge of recklessness in it, since the Castle test had just been finished.

Dr. LAPP. May I ask a question of Dr. Eisenbud? Is this permitted?

Representative COLE. Don't look at me.

Representative HOLIFIELD. I think——

Dr. LAPP. I would like to ask one single question.

Representative HOLIFIELD. You might ask the Chair a question.

Dr. LAPP. I would like to ask the Chair a question, as to what the roentgen dosage on the fallout on Troy, N. Y., was.

Representative HOLIFIELD. The Chair has been told, but the Chair has temporarily forgotten now. The Chair will ask Dr. Eisenbud if he recalls.

Mr. EISENBUD. Yes, sir. It has been variously estimated.

Representative HOLIFIELD. Is it an unclassified amount?

Mr. EISENBUD. It is unclassified. It was published 3 years ago. The upper limit of estimate is something under 100 milliroentgen. It loses about 1 milliroentgen. I would personally estimate it at about 10 milliroentgen.

Representative HOLIFIELD. The Chair thanks the gentleman for that information.

Representative COLE. Could I inquire, in order for the information to be helpful, if these samplings that occurred were related to what tests? When were the samplings taken which you say indicated an upper limit of 100 milliroentgen?

Mr. EISENBUD. I believe it was the third or fourth test of the series held in Nevada in the spring of 1953. There was a rain out over the Troy-Albany area which coincided with the passage of a cloud from Nevada. So that a very large percentage of this cloud was washed down.

Senator ANDERSON (presiding). Are there additional questions or statements?

Representative VAN ZANDT. Dr. Eisenbud, I understand your position is that the statement that Dr. Lapp attributes as being a reckless one was taken out of context.

Mr. EISENBUD. Yes, sir.

Dr. LAPP. Is it proper for me to respond? I have done a little arithmetic. Let us take 10 milliroentgens, as Dr. Eisenbud estimates, and we multiply 10 milliroentgens. That would be .01 roentgens by 10 to the sixth, which will give us 10 to the fourth, which is 10,000 roentgens.

Senator ANDERSON. 10,000 roentgens would kill everybody in sight.

Mr. EISENBUD. Yes.

Senator ANDERSON. So that would mean there would not be any immediate danger if you kill everybody in sight?

Representative PRICE. Mr. Chairman, one of the points that we do not want to overlook is that Dr. Lapp is trying to point out the responsibility of the Commission to release information as promptly as possible so that these types of statements would not be made. Is that not one of the reasons for you citing this statement?

Dr. LAPP. I really feel if we had better relations here between the press and the Atomic Energy Commission we could in a minute avoid much of this difficulty.

Representative PRICE. That is the reason I understood that you gave this example.

Dr. LAPP. Yes.

Senator ANDERSON. May I say, Mr. Eisenbud, that I am truly sorry that Dr. Lapp's quotation has caused any embarrassment. I want to repeat what I said before. I certainly regard you as a fine public servant doing a good job. I am very happy that you are here make your contribtuion today.

Mr. EISENBUD. Thank you, sir.

(The full statement of Dr. Ralph E. Lapp follows:)

STATEMENT OF RALPH E. LAPP ON RADIOACTIVE FALLOUT

EXPLANATORY NOTE

Mr. Holifield, I received your invitation to testify before this committee while I was in Japan. I cut short my trip in order to attend the hearings. May I

say that I appreciate very much this opportunity to appear here. I would like to add that I am very gratified that your investigations to date have thrown so much light on the problem of radioactive fallout. I believe that these hearings will stand as a landmark in the history of our knowledge about this relatively new phenomenon.

COMMENT ON DR. LIBBY

Appearing as I do after Dr. Libby, I would like to comment on his contributions to fallout. Dr. Libby has not only stimulated extensive research in fallout investigations such as Project Sunshine, but he has also taken the initiative in publication of his findings. I feel very strongly that he deserves a great deal of credit for his work on fallout. Were it not for Dr. Libby we might well be confronted with a considerably smaller body of knowledge about fallout than we have today.

MY INTEREST IN FALLOUT

I have had an active interest in atomic bomb phenomenology ever since I witnessed the Bikini Baker test in the summer of 1946. However, my interest in radioactive fallout was really stimulated by the 1954 Bravo test at Bikini. This was the test which resulted in radioactive contamination of the *Lucky Dragon No. 5*, a Japanese tuna trawler.

My initial interest in fallout centered upon civil defense. In this connection, I published a series of articles on fallout in the Bulletin of Atomic Scientists as follows:

November 1954: Civil Defense Faces New Peril
February 1955: Radioactive Fallout
June 1955: Radioactive Fallout III
November 1955: Global Fallout
September 1956: The "Humanitarian" H-Bomb
October 1956: Strontium Limits in Peace and War.

NATURE OF MY TESTIMONY

I am dividing my testimony into four parts:

I: General Remarks
II: Local Fallout
III: Remote Fallout
IV: Constructive Proposals

Because of the number and complexity of the topics covered, I am presenting my remarks in terse or fragmentary form. This will permit the committee to bypass topics of less importance and concentrate upon those of more concern.

PART I. GENERAL REMARKS

A. Necessity for numbers

Public confusion about fallout will continue to increase unless scientists can provide a quantitative or semiquantitive evaluation of the various hazards associated with fallout. Precision is probably not possible due to the nature of the hazards and we may have to be content with numbers which vary by a factor of 2, 3, or even 10. Th is committee has already performed a valuable service in narrowing the range of estimates made by individual witnesses.

B. Disagreement among scientists

The public is apt to conclude that if scientists cannot agree upon the hazard, then all is confusion. It would be nice if the scientists could all agree upon a quantitative estimate of the hazard, which could then be given to the public. Two unusual circumstances have combined to produce the current confusion on fallout.

First, the urgency of our times has focused attention upon problems for which science did not have textbook answers. Available knowledge was inadequate and research had to be initiated to provide answers.

Second, the ordinary process by which scientists argue out their answers was interdicted by the complexity of the problem and secrecy. Scientists outside the Atomic Energy Commission have full-time jobs and could scarcely be expected to tunnel into the complexities of the problem in a few leisure hours.

C. Responsibility of the Atomic Energy Commission

Considering these factors, I think that the AEC has the responsibility for providing the outside world with the facts about fallout as promptly as these become available. Scientists, technicians, and officials of the AEC must present only reasoned and careful estimates of the hazards based upon factual knowledge. Reckless or nonsubstantiated statements do a disservice to the AEC and to the Nation.

Example: Dr. Eisenbud is quoted in an article titled "Man Who Measures A-Fallout Belittles Danger" (Sunday News, New York, March 20, 1955) as follows: "The total fallout to date from all tests would have to be multiplied by a million to produce visible, deleterious effects except in areas close to the explosion, itself."

Example: Dr. Libby in a speech dated June 3, 1955, stated: "However, as far as immediate or somatic damage to the health is concerned, the fallout dosage rate as of January 1 of this year in the United States could be increased 15,000 times without hazard."

Example: Dr. Richard Doan while in Tokyo on May 13, 1957 stated that the bomb tests would not have "the slightest possible effect" on humans.

I do not label Dr. Libby's statement as reckless but interpose it to illustrate the spectrum of opinion being given to the public.

D. World interest in fallout

I am informed by a cable from Tokyo that the deliberations of this committee hearing are being "splashed across page 1" of the Japanese newspapers. This comes as no surprise to me for my trip through Japan alerted me to the overwhelming interest manifested there in atomic radiation.

The committee might be interested in my observation that fallout has become an acute weapon for propaganda. For example, I found that the Japanese scientists are actively studying the radioactivity of their tea because of the assertion from the Chinese mainland that Japanese tea is radioactive. Some people in Japan are so keenly aware of fallout that they take showers after being out in a rain. The great public outcry against the British Christmas Island tests, but there was no great demonstration against Soviet tests. It is a great victory for psychological warfare experts when they can induce selective sensitivity to fallout.

America puts itself in a bad light when it fails to present its case clearly to the world. Even casual analysis of the news reporting in this country will show that AEC pronouncements on fallout are not received with full credibility. This situation is obviously not in the full interests of national security.

E. The nature of biological data

It is inherent in the very nature of the biological research into the effects of radiation upon humans that a high degree of accuracy is not attainable, especially on a human experience basis. As Dr. Langham of the Los Alamos Laboratory has testified human experience with retention of radium 226 is the basis for setting upon a maximum permissible concentration (MPC) for radiostrontium (Sr–90). Yet our actual experience is confined to a small sample of acutely exposed individuals and a small sample of less acutely exposed people.

Actually, our concern should focus not upon acute effects in man which are highly unlikely from peacetime bomb testing, but rather with the chronic, debilitating long-term effects from irradiation of humans. We must be conscious of the need to appraise long-delayed effects, say, 50 years after entry of radioelements into the body. Here our knowledge is quite limited.

F. Radiation limits for a global population

I would like to stress the fact that consideration of safe limits for irradiation of the world's population is essentially a new problem. Prior to the awareness of global fallout, the International Commission on Radiological Protection made its recommendations for those who would be exposed to radiation in pursuit of their occupation. Such groups initially were numbered in the hundreds and then in the thousands as atomic energy came of age. Individuals within such groups were healthy adults exposed to known and restricted hazards; they were subject to administrative controls and medical supervision.

In setting up limits for a total population, we must take into account the varying radiosensitivity of individuals, the complete spectrum of age, the persistence of the hazards, the lack of medical control, the varying degrees of health of people and the variety of their diet. Yet it was not until last year that the

Atomic Energy Commission introduced the difference between an occupational MPC and a global MPC into its releases on fallout.

In view of the nature of our knowledge and the totality of the sample with which we are dealing, I would urge a big factor of safety in setting limits to bomb testing. It would be tragic to find some day that we had erred in setting the limits.

G. Soviet nuclear tests

On my recent trip to Japan, I learned that Japanese scientists collected sufficiently active samples from Russian tests to perform radiochemistry upon the bomb debris. I am informed that five Soviet tests produced a fallout on Japan from which scientists measured and identified the presence of uranium 237 (U–237). Soviet explosions characterized by such fallout were judged to be in the megaton range. These estimates are subject to considerable uncertainty but one authority told me that he estimated at least two bomb yields in the range of 10 megatons.

Two Soviet nuclear tests were observed to originate in the arctic region whereas the remaining tests took place in a region estimated to be Ozero Balkash (Lake Balkhash) which is southeast of the new coal area of Karaganda. The air mass trajectories from central Siberia frequently sweep across the islands of Japan, especially Hokkaido. They also produce tropospheric fallout over the United States as well. Here in Washington you could swipe a Kleenex over a car top and cause a Geiger counter to respond readily.

The presence of U–237 in the Soviet fallouts proves that the Soviets have achieved a compound fission-fusion or multiple-stage weapon. According to my information, this was first accomplished in September 1954.

I would like to add that I am informed by Japanese sources that Soviet tests produce 70 percent of the fallout observed on Japan. Pacific tests account for 20 percent and the Nevada shots add 10 percent.

PART II. LOCAL FALLOUT

Definition: By local fallout, I mean that which comes to earth within several hundred miles of the explosion site and is deposited within the first day or so. The following points are discussed with relation to the direct effects of external radiation. My interest centers upon the problem of civil defense in dealing with the radiation hazard in a contaminated area.

A. Areas of contamination

It is evident from the analyses such as Dr. Schafer presented to this committee that a nuclear attack upon the United States would involve an overlapping or smeared out pattern of bomb fallouts, especially over Northeastern United States. In making assessment of the radioactive power of bomb fallout, it is useful to introduce a new unit "the eternity roentgen square mile." This is a measure of the irradiating power of bomb fallout. By "eternity roentgen" I mean the total roentgens accumulated in dosage from 1 hour to eternity. This unit is then multiplied by square miles over which fallout occurs.

Example: To estimate the eternity roentgen square mile contamination from a 15 megaton explosion we proceed as follows. Assume that the ratio of fission to fusion energy release is 2:1. Then 10 megatons of fission energy will be involved. Assume a 50 percent local fallout. This yields 5 megatons of fission products in the fallout area. Simple calculation shows that 1 megaton of fission products could contaminate (if uniformly deposited at 1 hour) 1,000 square miles so that the 1 hour to infinity dose in open air would be 6,000 roentgens. Thus 5 mt. of fission products could raise this dosage to 30,000 r. Or if the area of fallout were greater, say, 5,000 square miles, the dosage would be 6,000 r.

An attack such as Dr. Schafer assumed involved 2,500 mt. of bomb yield and he specified "dirty weapons" surface burst. By "dirty" it is meant that the ratio of fission to fusion is fairly high. If we assume 2,000 mt. of fp (fission products) locally deposited this amounts to a total of 12 billion roentgen square miles of potential contamination. Obviously, this is a maximum since much fallout will occur after 1 hour; this will dissipate harmlessly in the air until it is deposited on the ground. Nontheless, the figure especially for surface burst bombs where local contamination will be maximized gives an indication of the magnitude of the fallout hazard. If any considerable fraction of this total figure is concentrated on a relatively small area, such as Northeastern United States industrial heartland, the corresponding radiation intensities will be severe.

Example: If a 1,000 mt. of fp concentrated upon Northeastern United States much of the region would be subject to a fallout of about 10,000 eternity roentgens. This would correspond to a fallout intensity of 2,000 r./hr. at 1 hr. I shall discuss the significance of such fallout in section C.

B. Clean and dirty bombs

The above discussion should make it obvious that the fallout from dirty weapons is of immense importance because of the area contaminable with a medium-weight attack. However, it may be useful to compare the damage areas of the two types of weapons.

A clean or relatively clean air burst bomb would have to depend upon blast and heat for its destructive effects. Consider, for example, the areas hit by the blast of a 20 mt. bomb.

Blast overpressure (pounds per square inch)	Distance in miles	Area in square miles
100	1.5	7
10	7.5	175
3	15,0	1,600

For purposes of comparison, one might select purely military targets such as air fields, missile sites and "hardened" targets which would require up to 100 pounds per square inch blast overpressure for destruction. Under such cases the aiming accuracy in delivery would have to be very great if you wished to "hit". A miss by as little as 2 miles with a clean bomb could be considered a complete miss. If one is concerned with population bombing and the criterion is the destruction of a framehouse, the 3 pounds per square inch blast would be appropriate. A greater aiming error would be allowable but one would not want to miss by more than 10 miles.

To complete the comparison, it is necessary to assess the persistence of the radioactive effect of fallout to discover whether such contamination would be effective in denying land to normal or to even emergency use.

I make this point, not to assert that there would be no military uses for clean bombs, but to emphasize that from the standpoint of civil defense, it might be very misleading to assume that an enemy would forego the use of dirty bombs.

C. Persistence of fallout

Witnesses before this committee have testified as to the rapid decay of fission products in fallout. It is true that a fresh mixture of bomb-produced fission products exhibits rapid decay. Half of the radioactivity, as measured from a time base at 1 hour, disappears in 32 hours. The AEC states in its report The Effects of High-Yield Nuclear Explosions (February 1955) "The main radioactivity of fallout decreases very rapidly with time—for the most part, within the first hours after the explosion."

Section 10.1 of the "Effects of Nuclear Weapons" (June 1957) states: "The radiation intensity decreases rapidly with time and except for areas of very high initial contamination, it ceases to be a serious hazard within a few weeks."

These statements, it seems to me, give the impression that civil defense has nothing to worry about after a few days, or a few weeks. I believe that the discussion in section A (part II) coupled with Dr. Schafer's estimates of the fallout intensities show that large areas of the United States could be contaminated to the extent of 2,000 roentgens per hour at 1 hour. The following schedule of roentgen dosages results:

From 1 hour [1] through end of 1st day	4,700 r.
From end of 1st day to end of 1st week	1,730 r.
From end of 1st week to end of 1st month	920 r.
From end of 1st month to end of 1st year	1,060 r.
From end of 1st year to 50 years [2]	840 r.

[1] The dosage of 4,700 r. depends upon fallout at 1 hour after detonation. Fallout at later times (i. e., farther downwind) would significantly reduce this first day dose.
[2] Terrain and weathering would play a significant role in reducing this dose.

If we look only at the decay rate, the decay seems rapid. Starting at 1 hour after the explosion, the rate would be 2,000 r./hr. At 7 hrs. it would decrease to 200 r./hr., at 1 day to 45 r./hr. At the end of 2 days it would be 20 r./hr. At

1 week it would be 4.2 r./hr. or 100 roentgens per day. At the end of 1 month it would be 17 r./day; this would decrease to 4 r./day at 100 days, and to 0.8 r./day at 1 year.

D. Significance of local fallout

I believe that the combination of the vast areas contaminable with high-yield thermonuclear weapons with the long term persistence of the fission products poses a problem for civil defense of great magnitude as different from that of the A-bomb as that was from the TNT bomb.

E. Genetic consequences of a 2,500 mt. attack upon United States

Assume, as in section II–A, that the United States is hit by a 2,500 megaton attack, in which some 2,000 mt. of fission products are deposited on the ground. As we have seen this can be expressed as a contamination equivalent to 12 billion roentgen square miles, where the roentgen as used here is the eternity roentgen. If we make the simplifying assumption that this contamination is spread uniformly over the continental United States, this will produce an eternity exposure of 4,000 roentgens (land area is 3 million square miles). In an actual situation this would be unevenly distributed but the probability is that exposures would be greatest nearest inhabited areas, so this calculation probably underestimates the effect.

Let us assume that people go into hiding and receive no signified radiation exposure in the first month after the attack. I grant that this is highly unlikely so the calculation is again underestimated. From 1 month to 30 years the exposure would average 20 percent of 4,000 roentgens or 800 r. Divide this in half to take account of weathering, so that we get 400 r. as the average exposure to every American who survives. We may now apply Dr. Crow's data of June 4 to this figure of 400 r. Instead of 2 billion children in the next generation we consider one-twentieth this figure. This means that we multiply Dr. Crow's values by 400 and divide by 0.1 (Dr. Crow's assumed 30-year exposure) times 20. Thus we multiply all his figures by a factor of 200. This yields:

Effect	1st generation	Total
a. Physical and mental defects	1,600,000	16,000,000
b. Stillbirths and childhood deaths	4,000,000	120,000,000
c. Embryonic and neonatal deaths	8,000,000	140,000,000
d. Intangible defects	(1)	----------

[1] A larger but unknown number.

In the first generation about 2 out of every 10 children would be genetically defective. The sum total of all deferred deaths from the attack would be 272 million or several times the number killed by the direct attack. In addition almost everyone would shoulder an increased genetic burden.

PART III. REMOTE FALLOUT

NOTE.—I believe that previous testimony and the roundtable discussions on the production, injection, transport, and fallout of radioactive debris from bomb explosions provide a more solid base for evaluating the hazard. It is obvious that in the area of the uptake of fission products there still remain some unknowns which future research and global survey will resolve. It is doubtful if the uncertainties inherent in estimating the biological effects of radiation will be resolved as readily. I wish to comment specifically upon several topics which I feel deserve amplification and emphasis.

A. The "present test rate"

This term has been used frequently before this committee as well as in the public domain during the past few years. Rarely has it been defined in a quantitative manner. To interpret the meaning of the present rate of testing one has to specify a precise number of megatons of fission products injected into the stratosphere.

I do not profess to have any inside information upon which to base an estimate of the present rate of testing. However, it is instructive to consider how the test rate has progressed since 1945. I am drawing upon data openly available and I apologize for the roughness of the data. Nonetheless, the progression of the annual increments to the curve may be worth considering.

The curve I shall plot covers the period from 1945 to 1957 with a projection to the future. Extrapolation of the curve will be considered. First, we plot the total fission yield of all bombs tested in each year. Up until 1952, and more generally until 1954, this total fission yield will correspond roughly to the total bomb yield. After that time corrections have been estimated for the fission fraction of the explosive yield. Second, we then estimate the fraction of the fission debris which is injected into the stratospheric reservoir and is globally dispersed. This fraction will depend upon bomb yield and firing conditions.

I claim no accuracy for the estimate and present the curve for qualitative illustration of the trend in the bomb test rate.

As long as weapons tests were confined to pure fission weapons of relatively low yield the global fallout of strontium 90 would be negligible. With higher yield fission weapons, more of the fission products began to be injected into the stratosphere and retained there for global distribution. However, because of the economy limits (cost of fissionable material) the global hazard was still quite small.

On November 1, 1952, the United States entered a new domain of weapons testing. The Soviet Union followed suit within a year. These tests were then followed by the Castle series of tests in the Pacific in the spring of 1954 when high-yield contaminating bombs were tested at Bikini. These tests added to the stratospheric reservoir the majority of the radiostrontium still present there. Dr. Langham of the Los Alamos Laboratory testified before this committee that one might assume an average rate of 10 megatons of fission products per year. This total of 50 Mt. for the past 5 years would check with the data that I have estimated.

In order to define the present test rate one has to wait until the end of the year, add up the Soviet, United States and United Kingdom contributions to the stratosphere and thus reach a reasonable figure. In the absence of international exchange of data, this is done through remote instrumentation.

B. A limit to bomb tests

Dr. Neuman in testifying before this committee arrived at a "safe" test rate of 2.2 megatons of stratospheric strontium 90 per year; i. e., the amount associated with the annual injection of strontium 90 produced in an explosion such that 2.2 megatons of fission energy inject their fission products into the stratosphere. Some time ago, I estimated on a similar line of reasoning that this "safe" limit would correspond to 3 megatons (plus or minus a factor of 3 times this value); i. e., as high as 9 or as low as 1 megaton per year. I believe this is in general agreement with the 2 to 10 megatons estimated by your roundtable discussion of May 29.

Superimposing these values upon the chart for the yearly test rates, it is seen that this "safe" limit was exceeded in 1954, 1956, and probably will be exceeded this year as well.

I believe the concept of a safe testing rate is of very great importance from a global health viewpoint. But the limit seems so low that it would appear that setting up a quota for each nation's annual testing would de doomed to the same fate as the attempt to control battleship construction in the 1920's.

But I believe that an internationally constituted monitoring system could keep systematic check on the level of fission products which fall out as a result of bomb tests. The publication of these measurements would have a profound effect on world opinion.

It would be of interest to learn from the Atomic Energy Commission the value for the safe annual limit which it assumed in its deliberations during the past 3 years.

C. A limit to war

There is obviously a great difference between the risks which a nation and its people take in time of war. During wartime the "safe" limit for the military application of thermonuclear weapons would be, at least in my opinion, 50 times greater than the peacetime safe limit. Whatever the value, the concept of a limit to the use of nuclear weapons in war is quite new. I have in mind here the inevitable lashback which an aggressor would suffer from the fallout of his own bombs. Dr. Libby, in his speech of January 19, 1956, estimated that between 330,000 and 440,000 megatons of bombs would have to be exploded before "the likelihood of untoward effects would be appreciable."

In view of the consequences to humanity, I wonder whether the Atomic Energy Commission or the Department of Defense has ever prepared a full study of the biological consequences of a nuclear war.

D. Evaluation of risk

Dr. Eisenbud's remark that he is not troubled by the hazard of giving milk containing traces of Sr-90 to his children illustrates, I believe, an extreme form in which a radiation risk may be assayed. The probability of injurious effect to a sample of three people is very small; from a personal viewpoint it is probably negligible. But if one applies the same probability of injury to 3 billion people, then even a very minute effect becomes significant to those whose lives are affected. Suppose we deal with a probability of one in a million. For a global population this would involve about 3,000 people. Such an effect would, from a personal viewpoint, constitute a very small risk. The same line of argument applies to Dr. Shields Warren's reference to the personal danger from the radiation emitted by the microgram of radium in his luminous wristwatch dial. The fact that he observes no visual change in the skin directly beneath the wristwatch proves nothing—certainly, it does not constitute a test of a radiation threshold.

If I may comment on the testimony of other expert witnesses who testified on Monday, June 3, I find Dr. H. L. Friedell's philosophy with regard to bomb tests rather whimsical. Apparently, Dr. Friedell believes we do not have enough data to evaluate the risk and we should proceed on a path of blissful optimism.

Testimony introduced on behalf of Dr. Jacob Furth by Dr. Shields Warren contains a recommendation that "the burden of decision rests not with biomedical investigations, but with military experts." In a matter so rooted in nuclear science and so veiled in conflicting opinions, I am reluctant to entrust the burden of the decision to military experts.

Dr. E. P. Cronkite cites three reports as authoritative in evaluation of strontium risks: (*a*) the United Nations report, (*b*) the British Medical Council report of June 1956, and (*c*) the National Academy of Sciences report of June 1956.

(*a*) So far as I know the United Nations report on strontium has not been concluded. I am informed it will not be published this year.

(*b*) With regard to the British report, I would call attention to the last sentence of that report. "Nevertheless, if the concentration in human bones showed signs of rising greatly beyond one-hundredth of that corresponding to the maximum permissible occupational level it would indicate the need for immediate consideration of the problem."

(*c*) With regard to the National Academy study, may I refer to page 60 of the general report, section 3: "However, if the testing programs of the several countries producing theromonuclear weapons were to intensify, strotospheric storage time may become a critical item in terms of the hazard to mankind."

Since the National Academy report was issued the United States, the U. S. S. R., and the United Kingdom have all tested theromonuclear weapons. I submit that the testing programs are intensifying.

E. Future nuclear tests

In assessing the future commitments of radioactive debris to the earth's atmosphere, we must deal with many unknowns. Had we attempted an estimate 5 years ago, prior to Castle-type weapons, we would have arrived at most misleading and optimistic projections. The end of weapon development is not in sight and no one can say that unexpected developments may not occur.

For example, may not smaller nations be stimulated by British success with thermonuclear type weapons and place maximum emphasis upon such development?

Additionally, can we be sure that a nation would restrain itself and not test a 100 megaton dirty weapon if military requirements and nuclear technology indicated that such a weapon was desirable?

Will the requirements of adapting maximum megatonnage to a small warhead put emphasis on further development of dirty type weapons?

We cannot answer these questions at this time, but we do know that a single weapons test of very high fission yield can add a strontium burden to the atmosphere far beyond the limits we have been discussing.

The United States has contributed the largest fraction of radiostrontium to the stratosphere and I think that it is most encouraging that the fullest discussion of the strontium fallout should occur in this country. I am not aware of any large body of published information on this subject of Soviet origin. It is known, however, that the Soviets are engaged in strontium studies.

In concluding this section, I would like again to stress Dr. Libby's contributions to this subject. They are of very great value and I feel sure that we would be in a much poorer position today to evaluate the strontium problem were it

not for Dr. Libby's personal interest in this field of investigation and the research which he has promoted so vigorously.

F. The strontium problem

It is clear from testimony given to this committee that data on the fallout of radiostrontium are becoming more firm as research results come in. I think that scientists can agree on the pattern of strontium fallout around the world. We are in a poorer position in our knowledge of strontium uptake in the biosphere. I am disturbed by fluctuations which have occurred in AEC statements on discrimination factors in the uptake of strontium into the food chain. Discrimination factors are high in the milk link of the food chain, but are much lower in foods consumed directly by humans. A discrimination factor of 7 is estimated by Dr. N. S. MacDonald of UCLA and Dr. W. Neuman estimates an average discrimination factor of 8.

Strontium 90 determinations in man must be expanded to assess the increase in strontium 90 burden with time. Careful determinations of natural strontium in humans deserve increased attention. We know that more strontium 90 will accumulate in humans as a result of bombs tested in the past and as a result of current tests. The determination as to how much of this radioelement may be tolerated safely is a matter for the biologists to discuss. This committee has heard a fairly wide range of opinion from its expert witnesses on the probable biological effects of Sr-90 levels in man. But it seems to me that even in this area some agreement was reached, especially when Dr. Shields Warren stated on June 3:

"I would be reluctant to see the average strontium 90 content of bones, particularly in children, go much above 10 times the present level."

Dr. Libby's speeches show that Sr-90 fallout will continue and the strontium 90 level in human bones will increase.

Unless restraints are imposed upon commitments of fission products to the atmosphere, it is only a matter of time before the strontium 90 level of Dr. Warren is reached.

PART IV. CONSTRUCTIVE PROPOSALS

A. Atomic Energy Commission information policy

I suggest that this committee or its parent committee may wish to review the information policy of the AEC with regard to nuclear weapon effects, with a view toward revising this policy so that information may be made available more promptly and completely. I believe that the national interest demands a much better relation between the press and the Atomic Energy Commission.

B. Report on the probable biological consequences of a nuclear war

I suggest that the Joint Committee on Atomic Energy might wish to recommend or sponsor the preparation of an analysis of the probable biological effect of nuclear warfare. It would be useful to investigate probable lashback effects from various levels of nuclear bombardment.

C. Data useful to civil defense

I believe that the committee's investigations have produced information of critical value to civil defense planning. It might be useful to have a summary report of these data transmitted to the Federal Civil Defense Administration. I have not seen many representatives of the Federal Civil Defense Administration at these hearings.

D. Research in long-range estimation of nuclear explosives

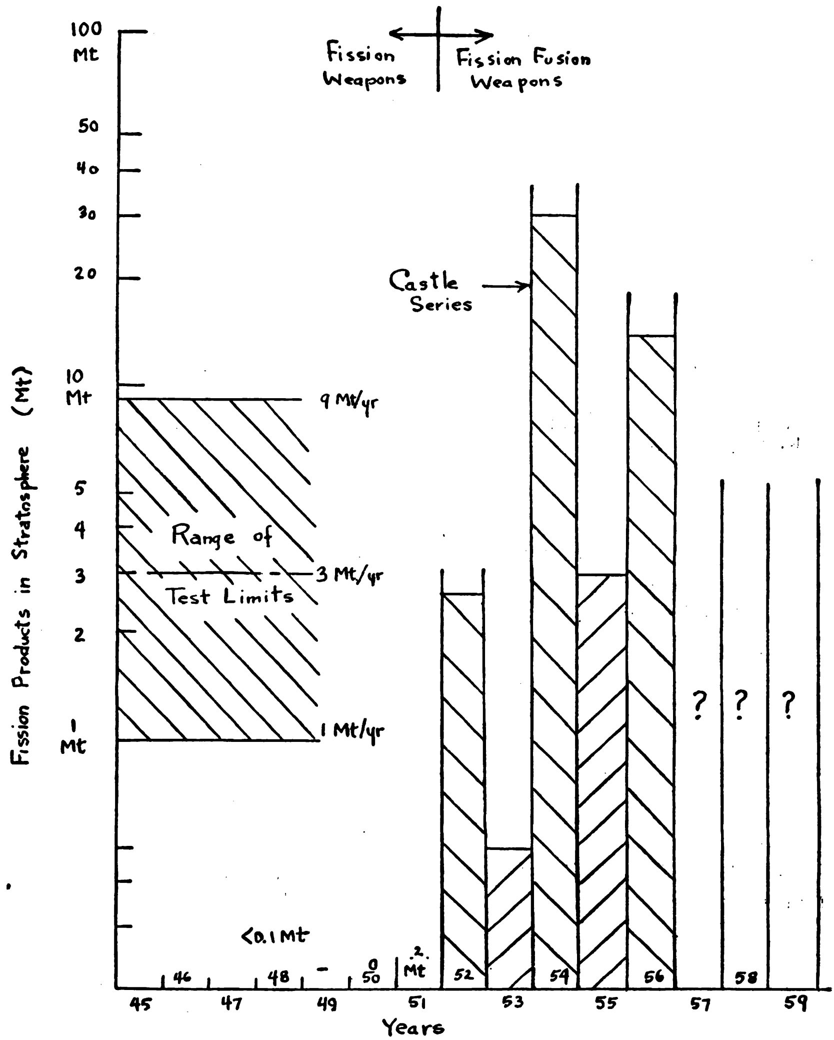
It is known that considerable effort has focused on long-range detection of nuclear detonations. Attention should be given to the declassification of such data as would bear upon evaluation of the radiostrontium problem. Other data would be most useful in discussion of the feasibility of policing an agreed upon test limit.

E. An annual fallout report

In view of the great public concern over fallout hazards, I would urge that the Atomic Energy Commission be required to issue an annual report on the degree of fallout and its uptake in biological systems. Perhaps such a report should be prepared by a university task force.

F. National radiation control

I would urge that the Congress continue its investigations of radiation hazards, extending them into the broader area of peacetime uses of radiation. I believe that the ever-increasing uses of radiation must be subject to legislative controls. Radiation protection in the United States needs uniform legal status.



Rough Estimate of Annual Additions to Stratosphere From Nuclear Weapons Tests of U.S.A And U.S.S.R [in Megatons of Fission Products]

Senator ANDERSON. Dr. Selove, we are happy to have you here today, proceed please.

STATEMENT OF DR. WALTER SELOVE, DEPARTMENT OF PHYSICS, UNIVERSITY OF PENNSYLVANIA [1]

Dr. SELOVE. I would like to thank the Joint Committee for inviting me to present testimony here. I would like to put before you insofar as time is available the results of some independent studies of the radiation hazards problem made primarily by the radiation hazards committee of the Federation of American Scientists.

The federation, as I believe you probably know, consists of scientists who are concerned with the interrelation between science and public affairs, and at the request of a number of members of the federation, a few of the members took on themselves the task of trying to gather such information as was available on the extent of the radiation hazards.

I have been a member of the radiation hazards committee for a year and a half or so and was recently elected chairman of that committee.

Representative COLE. What is the radiation hazards committee to which you refer, Dr. Selove?

Dr. SELOVE. What is it?

Representative COLE. Yes.

Dr. SELOVE. In the second paragraph of the prepared statement here you will see that at present the radiation hazards committee consists of several nuclear physicists, a biophysicist, a biochemist, a chemist, and a cancer research worker.

In the studies which this group has made of the radiation hazards problem we have also consulted with geneticists, and we have consulted with members of the Atomic Energy Commission, who I should say have been most cordial and helpful.

Representative COLE. What I would like to know, Dr. Selove, who is the sponsoring organization—of what organization is this radiation hazards committee of which you are a member?

Dr. SELOVE. This is a radiation hazards committee concerned with possible hazards from radiation sources of all kinds. It is one of the committees of the Federation of American Scientists which is a volunteer organization of scientists—of some of those scientists who are concerned with the impact and interrelations between science and public affairs.

One of the principal objectives of this statement is to emphasize that, although there is no important disagreement among scientists on the magnitude of the average dose of radiation due to fallout, conclusions which may appear to be in conflict with each other can be drawn with equal accuracy from the available facts.

I would like to quote from a report just prepared by the FAS radiation hazards committee which will illustrate this.

[1] Date and place of birth: 1921, Chicago, Ill. Education: Bachelor of science degree, physics, University of Chicago, 1942; doctor of philosophy degree, physics, University of Chicago, 1949. Work history: Assistant instructor, University of Chicago, 1942–43; staff member, M. I. T. Radiation Laboratory (radar), 1943–45; National Research Council predoctoral fellow, 1946–47; physicist, Argonne National Laboratory, 1947–49; instructor, assistant professor, Harvard University, 1950–56; on leave, University of California radiation laboratory, Livermore, 1953–54; member, editorial board, Review of Scientific Instruments, 1955–; National Science Foundation senior postdoctoral fellow, 1956–57; associate professor of physics, University of Pennsylvania, 1956–. (Submitted by witness.)

The committee study of the available scientific facts has led to two conclusions:

First: The added radiation hazard from continued nuclear weapons testing at the present rate is no greater than that from other radiation normally encountered. The radiation from testing will approach a level equivalent to the natural background radiation to which the human race has always been exposed. Similar radiation doses are obtained from annual chest and dental X-rays.

Second: This small added radiation, from whatever source, will cause many deaths.

The committee believes that both conclusions are scientifically correct, and in no way contradict each other.

Unfortunately, those who believe that we should continue testing in order to maintain a lead in nuclear weapons often emphasize the first conclusion and ignore the second. Similarly, those who believe that a test ban is desirable, since it may lessen international tension, often emphasize the second and ignore the first. The committee believes that both statements must be taken together since either alone is misleading.

Rather than try to cover fallout problems exhaustively I would like to restrict my remarks to just a few aspects of the problem, primarily concerned with the global and long-lasting effect of fallout and not taking up the question of close-in fallout effects.

One of the most important aspects of the problem I would like to emphasize is the uncertainties that remain as to just what the effects will be and how large the effects will be. That is, how many individuals will be affected.

There simply has not been sufficient time to learn what all the effects of fallout radiation may be. It is likely to be several decades before we know with much certainty. At present, however, it appears likely that the two principal effects of fallout will be the genetic effects from general gamma radiation and the production of leukemia and bone cancer by strontium 90. With regard to these effects, that is, the somatic effects, there is considerable disagreement as to whether small doses such as are involved in widespread fallout from tests will produce any effect at all. A considerable body of scientific opinion holds that it is very likely that even small doses will produce proportional effects and believes that there is some support for this conclusion both from experimental data and from theory.

Other scientists, as you have heard, are of the contrary opinion and believe there is probably a threshold for somatic effects.

All are agreed, however, that the true behavior cannot be determined from presently available data. I believe it is fair to say that on the basis of the data the pessimistic interpretation seems at least as reasonable as the optimistic interpretation.

In this connection, it should perhaps be emphasized that even if one takes the pessimistic interpretation; namely, that there is no threshold——

Senator ANDERSON. Are you reading from your prepared text?

Dr. SELOVE. No. I have some other statements here.

In connection with this question of pessimistic versus optimistic interpretation, I think it is worth emphasizing that even if one takes the pessimistic approach and assumes that production of leukemia and bone cancer are proportional to even small doses, it is still true that the probability that any given individual would be affected by the levels of radiation received from fallout from tests so far, is very small indeed.

For example, I have made a rough calculation for the type of effect to be expected from the radiation from a wristwatch. I come out with

the following number, regarding which I can go into more detail for you if you wish. The dose of radiation to the wrist from a wristwatch, according to the theory that even small doses may produce bone cancer, would have a certain probability of producing bone cancer, primarily a probability of producing it in the wrist, since the radiation from a wristwatch is concentrated in that area. I have calculated the effects of the dose from a typical wristwatch according to measurements which have been made of radiation from wristwatches. Suppose one had a million individuals not wearing wristwatches, on the one hand and a million individuals wearing wristwatches on the other. Now one would expect that among those not wearing wristwatches some 1,000 out of a million would eventually die, when they die, with bone cancer. This is a number of 1 in about 1,000 of all deaths normally occurring which is due to bone cancer.

Representative COLE. By that you mean that the cause of the death would have been the bone cancer?

Dr. SELOVE. That is correct. Those are statistics for the United States. Two thousand people in this country die every year from bone cancer. Then of the million who do not wear wristwatches, 1,000 would die of bone cancer.

Among those who wear wristwatches I calculate that 1,003 would die of bone cancer.

There would be a certain small effect. It is obviously such a small increase over the normally existing bone cancer and so small an effect on an absolute basis that obviously one individual has absolutely no worry as far as he himself is concerned as to the magnitude of this effect.

As has been emphasized before you by many witnesses, when one takes a very small percentage increase in some normally occurring effect and applies it to the very large population of the world then a considerable number of individuals may still be affected. It might be worthwhile giving a second example for the case which Mr. Holifield raised the other day, as to whether a mother should be concerned about letting her children drink milk which has the amount of strontium 90 in it that has been found to exist at present.

I calculate also on the basis of further numbers that I may present if you wish, and if time is available, that if you have again a number of children or adults drinking milk which has no strontium 90 in it and another group drinking milk which has the amount of strontium 90 currently present, then among those who drink milk with no strontium 90, 1 in 150 of them when they die will die of leukemia. This is a number based on statistics for the United States. It may be surprising to you that every year in the United States 10,000 people die of leukemia among a million and a half deaths. This is 1 in 150.

I calculate that if one drinks milk which contains the present amount of strontium 90 and if one uses the assumption that the effects of strontium 90 even in small doses are that proportionate amount of bone cancer and leukemia will be produced, then the probability that an individual will develop leukemia will be increased from 1 in 150 to 149.

Obviously from the standpoint of an individual, this is an extremely small number. This represents about a 1 percent increase in the probability that one would develop leukemia. The 1 percent increase translated into numbers which apply to a large part of the world popula-

tion, for example a country of the size of Japan means the following: If again we take for Japan—I do not have statistics available for this but I think we can use probably reasonably accurate numbers approximately the same as those in the United States—a number of deaths of leukemia per year which is probably 5,000 or 10,000 and if we have a 1 percent increase in that effect—and a 1 percent increase is the amount that one calculates from the kind of data presented to you by the expert witnesses in these fields—it means that in Japan as a result of the tests so far one may have each year at the present time 10,100 deaths from leukemia instead of the 10,000 which would normally occur.

Again this 100 additional deaths in one country—one should perhaps multiply this by some larger factor if one wants to consider the world as a whole—is a very small percentage compared to the million or so people who die in Japan every year, and even compared to the 10,000 or so who die of leukemia every year in Japan.

It is one purpose of this statement to gather together these numbers which have been presented to you by the various witnesses here and to show that depending on which aspect of the data one emphasizes one gets a result which has quite a different appearance, from the result which appears when the data is presented in another way.

To summarize this point, then, it has been estimated that some 10 percent of normal leukemia cases are due to natural background radiation, and a similar figure may also hold for bone cancer. The fallout radiation from past tests represents only a small percentage increase over natural radiation and consequently the effects of fallout radiation represent only a small percentage of increase over normal effects.

For example, even without fallout some 10 million people would develop leukemia or bone cancer over the next 30 years. This is an estimate based on the United States statistics. Because this number is so large, even the small percentage increase in radiation resulting from tests still can affect a considerable number of people.

Senator BRICKER. What percentage of those bone cancers are caused by natural background radiation?

Dr. SELOVE. There is not sufficient data to draw a conclusion. The conclusion has been reached by Dr. Lewis who testified before you that in the case of leukemia some 10 percent of the leukemia cases are very likely due to natural background radiation. Leukemia is a cancerlike disease of the blood. If the theory as to how cancer develops held by many geneticists, namely, that it is a mutationlike process, is correct, for one cancerlike disease leukemia, probably the same type of effect would hold for bone cancer.

Senator BRICKER. Is that generally accepted?

Dr. SELOVE. I am sure it is not widely accepted. These matters are just coming to be thought about.

Senator BRICKER. There may be other causes of bone cancer.

Dr. SELOVE. Even according to Dr. Lewis' testimony only 10 percent of leukemia would be due to radiation.

Senator BRICKER. Your statement is based on the premise that they are all caused from radiation?

Dr. SELOVE. No. I should say in this connection that the statistics for the United States are that each year some 10,000 individuals die of leukemia, and 2,000 from bone cancer. If we assume that approxi-

mately the same percentage of bone cancers are due to radiation as one would assume from Dr. Lewis' work is the case for leukemia, then we would have a very small number of bone cancer cases due to radiation as compared to the number of leukemia cases due to radiation.

If one lumps together leukemia and bone cancer it will not make much difference how accurate our estimate is of how much bone cancer is caused by natural radiation.

I would like to note that these figures I have presented are consistent with the recent estimate made by the radiation hazards committee of the British Atomic Scientists Association. I do not have the professional affiliation of the various members of that radiation hazards committee but I recognize one name on the list, that of Dr. Alexander Haddow, who is the director of a cancer research institute in Britain. That committee made an estimate, subject to the same assumption we have been discussing, that even small radiation doses produce proportional amounts of bone cancer. They estimated that some 50,000 cases of bone cancer might be expected to develop as a result of nuclear tests already carried out. This is essentially the same type of number I presented.

You have heard estimates of larger numbers of individuals affected. This number I believe represents a sort of median value. These numbers, it should be emphasized are extremely crude and approximate. There is simply not enough data to obtain very accurate numbers. The true effects might be easily 10 times larger than the numbers I am presenting. They might also be easily 10 times smaller. It is the very uncertainty that needs the strongest consideration.

A great deal of apparent disagreement on the dangers of fallout has been due to a difference in emphasis. The AEC has emphasized that the radiation from strontium 90 from tests so far will represent only a few percent increase from the natural background radiation, on the average. The AEC has further emphasized that this average increase in radiation due to strontium 90 is small compared to the additional radiation exposure many people receive simply as a result of living with a higher background radiation level than average or X-rays. Relative to other sources of radiation it is perfectly true that fallout radiation contributes at the present level of testing only a small additional increment. On the other hand it can be stated that even a small percentage increase over the natural background radiation is likely to harm a considerable number of individuals.

The likelihood that even a small percentage increase over background radiation will cause many deaths applies to radiation from other sources as well as to fallout radiation. It should be remarked that the very rapidly increasing awareness of the effects of radiation is already leading to greatly improved X-ray techniques.

Next is the effect of fluctuations. I think this affects the impact of the fallout problem on the people of the world.

The fact that fallout is not distributed with absolute uniformity among all the people of the world affects the evaluation of the fallout hazard in two important ways. First, as has been emphasized by many people, and particularly by Doctor William Neuman, if a "maximum permissible" level of fallout material, say of strontium 90, is agreed upon, then the world average level should not be allowed to go beyond a fraction of it, or else an appreciable part of the world pop-

ulation would be subjected to more than the "maximum permissible" level.

Second, the detectability of fallout effects, which to a considerable extent determines the psychological impact of the effects, will be increased as a result of variations in the amount of fallout, in the diet, and in the nature of the soil. Some 50,000 individuals may develop leukemia and bone cancer from strontium 90 due to tests so far. If these 50,000 were fairly uniformly spread over the world, they would probably be undetectable among the 3 million or so "normal" cases of bone cancer and the 10 million or so "normal" cases of leukemia which would be present even if there had been no fallout. But in actual fact some world areas will suffer more heavily than others, due to diet and soil nature, and due to the nonuniform distribution of fallout. Although the world average increase in leukemia or bone cancer, for 50,000 total cases due to fallout, would be only 1 in about 60 normally occurring cases of bone cancer, or 1 in about 500 normally occurring cases of leukemia, the relative increase in some areas might be as high as about 1 case for every normally occurring case of bone cancer. Even such a 100 percent effect, from tests so far, might be hard to detect, because the normal incidence of bone cancer is so low, and the number of people subjected to extreme levels is probably very limited.

Is there a danger from test fallout?

The two principal effects of fallout appear to be the genetic effects from general gamma radiation, and the production of leukemia and bone cancer by strontium 90. Scientists are agreed that genetic effects are produced even by small amounts of radiation. With regard to somatic effects, such as cancer, a considerable body of scientific opinion holds, with some support from experimental data and with some basis in theory, that these, also, can be produced even by small doses of radiation. On the assumption that this is true, it can be estimated that the number of individuals likely to be directly harmed in the coming generation by strontium 90 will probably be greater than the number showing genetic effects in that generation—although, for a given amount of fallout, the genetic effects will persist for many generations and will eventually cause direct injury to a total number of persons comparable to that affected by strontium 90. In terms of the immediate impact, therefore, we can concentrate our attention on strontium 90.

In regard to the genetic effect of fallout, Warren Weaver, vice president of the Rockefeller Foundation, and Chairman of the National Academy of Sciences Committee on the Genetic Effects of Atomic Radiation, estimated before a Senate subcommittee on January 16 that radioactive fallout from nuclear weapons testing to date will account for some 6,000 of the 30 million "handicapped" babies to be born in the coming generation. In regard to the effects of strontium 90, estimates quoted previously indicate that some 50,000 individuals over the next 30 years may develop leukemia or bone cancer as a result of tests to date.

How much should one be concerned about fallout effects of this magnitude? This is not a question which can be answered on scientific grounds. Even if one accepts the interpretation of the data presented above as a basis for estimating the number of individuals who will show genetic or somatic effects as a result of the 50 megatons—mil-

lions of tons of TNT equivalent—fission yield of tests so far, there are a number of other factors that must be carefully weighed before final judgment can be reached on the significance of the hazard. Probably no absolute evaluation will be possible, but instead, the evaluation will have to be made relative to the problem of securing peace in the world and in relation to the moral problems involved.

A discussion of some of these questions would take us out of the area at which this statement is directed, but it does seem desirable to emphasize that three of the pertinent factors which must be considered are:

(1) The uncertainties as to the number of individuals affected. The number may be smaller than 50,000, or larger. And the remaining uncertainties as to what all the effects of fallout radiation will be;

(2) The size of the number, 50,000, relative to the numbers of people harmed by other reducible effects; and

(3) The fact that the fallout effects are global, involving citizens primarily of countries other than the testing countries.

The global effects of fallout—as opposed to the more local effects—come almost exclusively from explosions of large nuclear weapons; a single one of these can produce as much worldwide fallout as a thousand bombs of the size used at Hiroshima. Those who consider the further development of large nuclear weapons necessary for military security view the probable effects of fallout as a small addition to other hazards of day-to-day living. Those who consider that the further development of large nuclear weapons moves the world away from peace rather than toward it of course do not feel that the military desirability of such weapons justifies the probable fallout effects of tests. Finally, there is a third group who, while not certain whether the further development of large weapons is likely to be useful, feel that in view of the uncertainties as to the nature and magnitude of fallout effects, and in view of the international political impact that testing of large nuclear weapons produces in the involuntarily exposed majority of the world, the nuclear testing powers would be well advised to exercise strong restraint with regard to tests producing further significant amounts of fallout.

As new nations enter the nuclear testing program, it can be expected that they will be interested in testing bomb types which produce a great deal of fallout. There are two dominant reasons for this:

First, about the most economical way possible to increase the yield of a large bomb is to use an outer shell of natural uranium. This leads to an inexpensive large energy release, but also to a large release of fission products—the worst kind of fallout.

Second, a large amount of fallout increases the devastating power of a nuclear bomb. The addition of a shell of natural uranium to a large thermonuclear bomb can increase the devastating fallout to a very much greater degree, for example, than the addition of cobalt to make a cobalt bomb, and moreover can at the same time increase the energy release by a large amount, which a cobalt shell will not do.

Although the United States appears to have turned its efforts to designing nuclear weapons which produce less fallout the U. S. S. R. does not appear to have followed suit as yet. While the United States Pacific tests of last spring did not add very appreciably to the stron-

tium 90 in this country, the first four Russian test explosions of last fall resulted in an increase of about one-third in the strontium 90 concentration in United States soil, within a period of a few weeks. Since that time, the U. S. S. R. has set off at least eight additional nuclear explosions—as of May 15. No information of any precision has as yet been released on the size of these explosions and on the amount of radioactive fallout resulting from them.

The amount of testing which can be tolerated.

I would like to ask Senator Anderson what sort of time scale you would like to proceed on. I can cut this short.

Senator ANDERSON. I have been trying to find out whether we should go ahead with the seminar we had scheduled. If it is agreeable for the other members and participants I would like to suggest that we do not go ahead with it. After all, 6 hours of hearing in 1 day is quite a little bit. If we are not going ahead with it, then I would say if you could conclude in the next 5 or 10 minutes, then there might be questions and we can conclude this afternoon.

Representative COLE. Mr. Chairman, I can only say I exhausted my absorptive powers an hour or so ago.

Senator ANDERSON. I would like to say to the participants that it is very difficult to those of us who are not scientists to try to keep up with papers that are presented and not do what Congressman Cole has just suggested. He has been a faithful attender of these hearings and trying his best to absorb it. It is unjust to him and to the participants.

If there is no vigorous and violent exception I will announce now that the seminar will not be held at the conclusion of this, but we hope to start off with it in a preliminary fashion tomorrow. Maybe it will give us a chance to therefore develop it.

I would ask the witness if he does not mind to try to conclude in 10 minutes.

Is there any objection? If not, you may proceed.

As you know, I am very much interested in the Federation of American Scientists and devoted to their program.

Dr. SELOVE. I would like to introduce in the record at the end of this testimony a copy of the report which the Radiation Hazards Committee has prepared, and if there are any questions we can discuss it further tomorrow.

I think it is useful to put the fallout problem in perspective through a look at some of the numbers of individuals affiected by fallout problems as compared to those affected by other related effects and some of these numbers are written out in this report.

(The report above referred to together with two statements by Dr. Selove follow:)

WORLDWIDE FALLOUT FROM H-BOMB TESTING—ALARMING OR NEGLIGIBLE?

Written by the Radiation Hazards Committee of the Federation of American Scientists

For almost a year highly qualified scientists have been making apparently conflicting statements on the hazards of fallout from continued nuclear weapons testing. Because of the existence of such conflicting statements, the radiation hazards committee has felt it desirable to make an independent and objective study of this important issue.

After 6 months of study and discussion the committee has reached complete agreement on the scientific facts of worldwide fallout and its hazard, and on the scientific conclusions that can be drawn from these facts.

The members are also agreed that arguments for or against the banning of nuclear weapons tests must be based primarily on moral grounds and on considerations of international affairs, and not purely on a scientific evaluation of the radiation hazards.

The committee study of the available scientific facts has led to two conclusions:

First: The added radiation hazard from continued nuclear weapons testing, at the present rate, is no greater than that from other radiations normally encountered. The radiation from testing will approach a level equivalent to the natural background radiation to which the human race has always been exposed. Similar radiation doses are obtained from annual chest and dental X-rays.

Second: This small added radiation, from whatever source, will cause many deaths.

The committee believes that both conclusions are scientifically correct, and in no way contradict each other.

Unfortunately, those who believe that we should continue testing in order to maintain a lead in nuclear weapons often emphasize the first conclusion and ignore the second. Similarly those who believe that a test ban is desirable, since it may lessen international tension, often emphasize the second and ignore the first. The committee believes that both statements must be taken together, since either alone is misleading.

How is it that both statements are correct? Why are they not contradictory? Only by an examination of the facts can these questions be answered.

1. OUR NORMAL RADIATION BACKGROUND

One must first recognize that the human race has always been subjected to a continuing radiation dose from natural, unavoidable causes such as cosmic radiation from outer space and natural radioactivity in earth and rocks. For comparative purposes we have taken as standard the normal, unavoidable, radiation experienced by a person living in a frame house in Germantown, Pa.

The figures below show that a person living in a stone house in Denver experiences a background radiation 35 percent higher than the Germantown resident. Other similar variations occur, owing to differences in the radium content of the drinking water, the wearing of a luminous dial wristwatch, etc. Many of us experience even larger doses from annual dental or chest X-rays.

How will the radiation dose from continued H-bomb testing compare with these "normal" radiations?

	Added radiation dose above the natural background dose received by a Germantown resident living in a frame house (percent)
"Natural" causes:	
Living in a brick or stone house	20
Living at 5,000 feet altitude (Denver, Colo.)	15
Total additional background for a person living in a stone house in Denver	35
Other causes:	
Wearing a luminous dial wristwatch	20
Having an annual chest X-ray	From 10 to 200

2. ADDED RADIATION FROM NUCLEAR WEAPONS TESTING

The radiation hazards from weapons testing that are the most serious are first the hazard to individuals due to the accumulation of radioactive strontium in the bone, and second the genetic hazard to future generations due to increased numbers of harmful mutations produced by the general rise in the external radiation background.

Considering first the bone radiation from strontium, it has been verified that radioactive strontium from weapons already tested is now accumulating on the ground. Since strontium is chemically similar to calcium, it is being taken up by plants and through our food chain is passing into our bodies and is being stored in our bones. Here it emits radiations, causing an increase in our bone dose over that from natural causes.

	Percent
Present (1955) average annual dose to human bone from strontium from past tests	0.2
Average annual strontium bone dose in 1970 if no more weapons are exployed	5
Average annual strontium bone dose by the year 2000 if tests continue	35

If weapons testing continues at the present rate, our children and grandchildren will on the average receive a bone dose of radiation 35 percent again as much as that received from natural causes.

Turning next to the radiation that may be genetically harmful to future generations, it is mainly the increase in external radiations that must be considered rather than internal radiations such as bone strontium. If nuclear weapons testing continues at the present rate the genetic dose will rise by 2 percent of the normal background dose. On the average we receive a 60 percent genetic dose from annual medical and dental diagnostic X-rays.

What will be the effect of fallout radiation doses as small as a bone dose 35 percent of natural background, or a genetic dose 2 percent of natural background?

Cause:	*Added radiation dose—Above the natural background dose received by a Germantown resident living in a frame house (percent)*
Average added genetic dose if tests continue at the present rate	2
Present average added genetic dose per year per person in the United States from X-rays	60

8. THE EFFECTS OF RADIATIONS

(a) The strontium hazard

Radiations in large doses are definitely known to produce leukemia and bone cancer, and at high dose levels the incidence is proportional to the dose. But what is the effect of small doses? For leukemia, evidence has been obtained that indicates that the incidence is directly proportional to the radiation received, and that about one-tenth of all present cases are due to normal background radiation. It is reasonable to assume that the same is also true for bone cancer.

While these interpretations are not yet rigidly proved, they are reasonable conclusions from the data and we can use them as the basis for estimating the extent of radiation effects.

There are 12,000 deaths annually in the United States from leukemia and bone cancer. If one-tenth of these cases are due to the natural radiation background, then an added radiation dose 35 percent of natural background, whether from continued H-bomb testing or from annual chest X-rays for all people, would be estimated to produce 400 additional deaths from bone cancer and leukemia in the United States per year. Over one generation of 30 years this figure would total 12,000 deaths. Many more deaths will be produced outside the United States by continued testing.

Deaths per year per 5 million people in the United States. (Approximately the population of greater Philadelphia)

Deaths per year from all causes	[1] 50, 000
Deaths per year from motor accidents	1, 100
Deaths per year from bone cancer and leukemia	380
Estimated present deaths per year from bone cancer and leukemia caused by natural background radiation	38
Estimated added deaths per year from bone cancer and leukemia for those living in stone houses at 5,000 feet altitude	13
Estimated aded deaths per year from bone cancer and leukemia from bone cancer and leukemia by 2000 A. D. due to continued testing	13
Estimated added bone cancer and leukemia deaths per year in 1970 from weapons already exploded	[2] 2

[1] Per 5 million people.
[2] Per 5 million people.

The above figures are for the United States only. They are probably also correst for the rest of the western world, but may be incorrect for those parts of the world where the death rate from other causes is much higher than in the western world.

(b) *The genetic hazard*

Mutations, or changes in the hereditary material passed on from parent to offspring, are known to be produced by radiation as well as by chemical and other causes, many unknown.

Geneticists are agreed that any increase in the mutation rate is bad, and they are also agreed that any added radiation dose will increase the mutation rate; the larger the dose the greater the number of mutations produced.

By how much does the mutuation rate in man increase, for an added dose of 2 percent of the natural background (from continued testing)? Or for an added dose of 60 percent of the natural background (the average X-ray dose per person under 30 in the United States)?

The absolute answers to these questions are not known. We can say, though, that in the United States the increasing use of X-rays and fluoroscopy for medical and dental diagnosis is a very much greater genetic hazard than is the increased radition from nuclear-weapons testing.

4. NUCLEAR WAR

Both those who favor continued H-bomb testing and those who favor a test ban are agreed that a major nuclear war would be a world catastrophe from which civilization might not rise again. They only disagree on the best method of averting such a war. Apart from the death, injury and destruction caused at the time, the radiation background would be raised many times above that from continued testing, and would result in further hundreds of millions of deaths in the years following the war.

CONCLUSIONS

While the scientific evidence discussed above is admittedly not complete, it is complete enough to allow reasonable conclusions to be made.

First, the radiation hazard from continued nuclear-weapons testing at the present rate is no greater than that from other radiations normally encountered.

Second, even this small added radiation will cause many deaths.

Third, even more lives are endangered by other radiation hazards such as from X-ray examinations. In the case of X-ray examinations the advantages are usually important enough to outweigh the disadvantages. The medical profession is alert to this problem and is taking active measures to reduce the exposure to a minimum.

Will continued testing lead to a hazard that is alarming?

If one believes that even one death from fallout is too many, and that no nation should subject other peoples to the effects of fallout without their consent, then the answer to the question is "Yes."

If, on the other hand, one believes that the security of the country depends on continued testing, then the answer to the question is, "No; it is a small price to pay for security."

Each person, in trying to answer these questions for himself, must make personal judgments based on the moral problems involved and on the problem of maintaining peace.

THE RADIATION HAZARDS COMMITTEE OF THE FEDERATION OF AMERICAN SCIENTISTS

Dr. John R. Pruett, nuclear physicist, associate professor of physics, Bryn Mawr College, Bryn Mawr, Pa.

SUMMARY OF REMARKS ON RADIOACTIVE FALLOUT PRESENTED BY WALTER SELOVE TO THE JOINT COMMITTEE ON ATOMIC ENERGY AT ITS OPEN HEARINGS

Although there is no important disagreement among scientists on the magnitude of the average dose of radiation due to fallout, conclusions apparently in conflict with each other can be drawn with equal accuracy from the available facts. As stated in a report just prepared by the radiation hazards committee of the Federation of American Scientists, the available scientific facts lead to two conclusions:

"First, the added radiation hazard from continued nuclear weapons testing at the present rate is no greater than that from other radiation normally encountered. The radiation from testing will approach a level equivalent to the natural background radiation to which the human race has always been exposed. Similar radiation doses are obtained from annual chest and dental X-rays.

"Second, this small, added radiation, from whatever source, will cause many deaths.

"The committee believes that both conclusions are scientifically correct, and in no way contradict each other.

"Unfortunately, those who believe that we should continue testing in order to maintain a lead in nuclear weapons often emphasize the first conclusion and ignore the second. Similarly, those who believe that a test ban is desirable, since it may lessen international tension, often emphasize the second and ignore the first. The committee believes that both statements must be taken together, since either alone is misleading."

There has not been sufficient time to learn what all the effects of fallout radiation may be. It is likely to be 10 or 20 years or more before we know with much certainty. At present, however, it appears likely that the two principal effects of fallout will be the genetic effects from general gamma radiation, and the production of leukemia and bone cancer by strontium 90.

Rough estimates can be made of the number of individuals likely to show these effects. The estimates are that, from tests through 1956, some 6,000 individuals throughout the world will show serious genetic effects in the next 30 years, and probably also some 50,000 will develop leukemia or bone cancer. (The genetic effects of a given amount of radiation will persist for many generations, and the total number of individuals ultimately affected genetically, from a given amount of fallout, will be comparable to the total number affected by strontium 90.) These estimates can only be made approximately—the correct numbers may be several times larger or several times smaller.

The fallout radiation from past tests represents only a small percentage increase over natural radiation (cosmic rays, natural radioactivity), and consequently the effects represent only a small percentage increase over "normal" effects. For example, even without fallout some 10 to 20 million people would develop leukemia over the next 30 years. Because this number is so large, even the small percentage increase in radiation, resulting from tests, still can affect such a considerable number of individuals as 50,000.

Should fallout effects of this magnitude be called "large," or "small"? This is not a question which can be answered on scientific grounds. A personal judgment is necessarily involved, based on the problem of securing peace in the world and on moral questions. Some of the factors which must be considered are (1) the uncertainties as to the nature and magnitude of fallout effects, (2) the size of the number 50,000 relative to the numbers of people harmed by other reducible effects, and (3) the fact that fallout effects are globel, involving peoples primarily outside of the testing countries.

As new nations enter the nuclear testing program, it can be expected that they will be interested in testing bomb types which produce a great deal of fallout. There are two dominant reasons for this: First, about the most economical way possible to increase the yield of a large bomb is to use an outer shell of natural uranium. This leads to an inexpensive large energy release, but also to a large release of fission products—the worst kind of fallout. Second, a large amount of fallout increases the devastating power of a nuclear bomb. The addition of a shell of natural uranium to a large thermonuclear bomb can increase the devastating fallout to a very much greater degree, for example, then the addition of cobalt to make a "cobalt bomb," and moreover can at the same time increase the energy release by a large amount, which a cobalt shell will not do.

Although the United States appears to have turned its efforts to designing nuclear weapons which produce less fallout, the U. S. S. R. does not appear to have followed suit as yet. While the United States Pacific tests of last spring

did not add very appreciably to the strontium 90 in this country, the first four Russian test explosions of last fall resulted in an increase of about one-third in the strontium 90 concentration in United States soil, within a period of a few weeks.

Official evaluations of the strontium 90 hazard have generally been given in terms of a "maximum permissible concentration" (MPC). The use of such a term is unfortunate, since it implies that the immediate and long-term effects of small amounts of strontium 90 in human bones are known with precision. They are not. Furthermore, it has been noted by many specialists that a "maximum permissible" dose is not necessarily a safe dose. It is possible to estimate from available data that, if large numbers of people are given a "permissible" dose, or one-tenth microcurie of strontium 90, then it is likely that about one in a thousand will develop bone cancer in his lifetime.

The uncertainty in the specification of a "permissible" level is indicated by the fact that the AEC has recently felt it advisable to revise downwards the strontium 90 level considered "permissible," to one-tenth of the value formerly used—namely, to one-tenth microcurie for the "standard" man. This has brought the AEC "permissible" level into agreement with that recommended for "large populations" by the International Commission on Radiological Protection. No recommendation has been given for the case that the entire world population is exposed; for this case, there is good reason to take the "acceptable" value as being still smaller.

The setting of a "tolerance" level for strontium 90 is arbitrary. On the assumption that even small amounts of radiation will produce proportionate amounts of leukemia and bone cancer, it can be estimated that a worldwide average strontium 90 level equal to the (new) "permissible" level would be likely to produce several million cases of leukemia and bone cancer. (A worldwide average level equal to the old "permissible" level would correspondingly be likely to produce several tens of millions of cases of leukemia and bone cancer.) On the basis of these estimates, one would hardly be willing to permit the world average strontium 90 level to come at all near the "permissible" level.

Although the setting of a "tolerance" level is arbitrary, the strontium 90 hazard from further testing can be measured against the yardstick of the amount of strontium 90 already released by tests to date. By such a yardstick, it could reasonably be argued that an increase of, say, 1 part in 1,000 in the amount of strontium 90 already distributed globally would hardly be considered catastrophic. An increase of that amount would be produced by some 50 kilotons (thousand tons of TNT equivalent) of fission yield—2 or 3 of the small bombs used to destroy Hiroshima.

The explosion of megaton-range weapons may or may not produce large amounts of fallout, depending on the bomb design—in particular, depending on whether a large part of the energy release comes from fission. It would take only a few bombs of a type releasing some 10 megatons of fission energy to double the total global fallout now existing. It is clear that so far as radiation hazard is concerned, for bombs of the types which have been tested so far, attention can be confined to the large bombs. As to the question of how much we should be concerned over a doubling, say, of the fallout produced so far, that is a matter into which many complex factors enter, as discussed previously, and no answer can be given on scientific grounds alone.

Although there is much room for disagreement on evoluation of the available data as to the results of fallout from tests, there is no disagreement as to the utter catastrophe that would result from a full-scale nuclear war. Hundreds of millions of people would be killed outright by blast, fire, and radiation, hundreds of millions more would die from the later effects of radiation injury, further comparable numbers in succeeding generations would suffer from genetic effects resulting from the radiation, and large parts of the devastated countries would be not only destroyed but made uninhabitable for extended periods.

The AEC is to be highly commended for the detailed measurements it has made on fallout, and for the steady release of the results of these measurements. However, the AEC has the dual responsibility of conducting a weapons development program and of evaluating the fallout hazard. It can readily be seen that decisions felt to be necessary in one area might conflict with and unduly influence decisions in the other. Because of these conflicting responsibilities, it may legitimately be questioned whether both functions belong in the same agency.

The suggestion has been made that an independent group of qualified scientists be appointed to take over the study and evaluation of fallout hazard and other radiation problems as well. In 1955, the National Academy of Sciences appointed a group to conduct such a study. The report submitted by that group was prepared over a year ago. Since that time, many new data have become available and many highly qualified specialists have expressed criticisms of the AEC's treatment of fallout problems. It is very desirable that appraisal of these problems be brought up to date. It can be expected that a group chosen to include representation of differing points of view can arrive at agreement on an interpretation of the data which can serve as an authoritative basis for policy decisions regarding future weapons testing.

We are at the present time forced into the difficult position of having to make decisions on a problem that we do not fully understand. The data on hand, however, do tell us this much: The fallout radiation from past tests will constitute over the next few decades a small percentage increase over background radiation. It is estimated that even this small percentage increase will cause genetic changes affecting some tens of thousands of individuals over a number of generations, and will probably also produce leukemia or bone cancer in a comparable number of individuals over the next few decades. The fallout effects will increase with the amount of fission yield in future tests. Each small explosion will contribute only a small addition to the fallout radiation already produced; each large explosion can contribute an appreciable addition.

It should be emphasized that the effects of nuclear tests are thousands of times smaller than the effects which would result from a nuclear war. While there is no disagreement that nuclear war would be a disaster which we cannot afford, there is disagreement on the best means of avoiding such a war, and some of that disagreement seems to have spilled over into the area of evaluation of the fallout hazard.

An objective scientific evaluation of the radiation hazard from fallout can be, and should be made independent of any policy or military considerations. The extensive information being compiled at these hearings will be of considerable help in arriving at such an evaluation.

Testimony on Radioactive Fallout

By Prof. Walter Selove, chairman, radiation hazards committee, Federation of American Scientists before the Joint Congressional Committee on Atomic Energy

I am Walter Selove, associate professor of physics at the University of Pennsylvania. I have been a member of the radiation hazards committee of the Federation of American Scientists (FAS), and was recently elected chairman of that committee. The prepared statement which follows is presented with the approval of the national executive committee of the FAS.

INTRODUCTION

A principal object of this statement is to emphasize that, although there is no important disagreement among scientists on the magnitude of the average dose of radiation due to fallout, conclusions which may appear to be in conflict with each other can be drawn with equal accuracy from the available facts. I should like in a moment to quote from a report just prepared by the FAS radiation hazards committee.

The FAS radiation hazards committee consists of several nuclear physicists, a biophysicist, a biochemist, a chemist, and a cancer research worker. This committee has felt it desirable to make an independent study of the available facts on fallout, and has tried to understand the basis of the apparent disagreement in the various statements on fallout hazards from qualified scientists. I now quote from the report just prepared:

"The committee study of the available scientific facts has led to two conclusions:

"First: The added radiation hazard from continued nuclear weapons testing at the present rate is no greater than that from other radiation normally encountered. The radiation from testing will approach a level equivalent to the natural background radiation to which the human race has always been exposed. Similar radiation doses are obtained from annual chest and dental X-rays.

"Second: This small added radiation, from whatever source, will cause many deaths.

"The committee believes that both conclusions are scientifically correct, and in no way contradict each other.

"Unfortunately, those who believe that we should continue testing in order to maintain a lead in nuclear weapons often emphasize the first conclusion and ignore the second. Similarly, those who believe that a test ban is desirable, since it may lessen international tension, often emphasize the second and ignore the first. The committee believes that both statements must be taken together, since either alone is misleading."

I shall shortly discuss these apparently conflicting conclusions in more detail; I wish here, however, to quote further from the final part of this report:

"While the scientific evidence * * * is admittedly not complete, it is complete enough to allow reasonable conclusions to be made:

"First: The radiation hazard from continued nuclear weapons testing at the present rate is no greater than that from other radiation normally encountered.

"Second: Even this small added radiation will cause many deaths.

"Third: Even more lives are endangered by other radiation hazards, such as from X-ray examinations.

"In the case of X-ray examinations, the advantages are usually important enough to outweigh the disadvantages. The medical profession is alert to this problem and is taking active measures to reduce the exposure to a minimum.

"Will continued testing lead to a hazard that is alarming?

"If one believes, as does Dr. Albert Schweitzer, that continued weapons development will not contribute to security, and that no nation should subject other peoples involuntarily to the effects of fallout, then obviously even one death from fallout is too many and the answer to the question is 'Yes.'

"If, on the other hand, one believes, as does AEC Commissioner Libby, that the security of the country depends on continued testing, then the answer to the question is 'No, the hazard is a small price to pay for security.'

"Each person, in trying to answer these questions for himself, must make personal judgments based on the moral problems involved and on the problem of securing peace."

The members of the committee are agreed that:

"* * * arguments for or against banning nuclear weapons tests must be based primarily on moral grounds and on considerations of international affairs, and not purely on a scientific evaluation of the rediation hazards."

I should like to confine this written statement to a discussion of the scientific questions involved, and will not present in it any evaluation as to whether the fallout hazard from tests is alarming or negligible. I omit presenting any such evaluation in this statement because it cannot be made on scientific grounds alone, and I wish to try to follow the Joint Committee's request to distinguish clearly between fact and opinion.

Rather than trying to cover fallout problems exhaustively, I wish to focus these remarks on a few aspects of the matter, primarily concerned with the global and long-lasting part of fallout.

UNCERTAINTIES IN NATURE AND MAGNITUDE OF EFFECTS

Strontium 90 is generally agreed to be the most worrisome component of fallout at the present time. The energy resulting from the radioactive decay of strontium 90 is only about one-two-hundredths of all the radioactive energy in fallout. Nevertheless, strontium 90 is one of the most important of the fallout components because of its long persistence and its concentration into a relatively small part of the human body—the skeleton. In regard to worldwide effect, it does not appear at present that any other fallout component presents a hazard comparable to that of strontium 90, but I do not believe it has been demonstrated beyond reasonable doubt that no other fallout component is concentrated, perhaps in some particular organ, perhaps through the food chain, to a level likely to present an appreciable hazard.

It must be said that no one knows with certainty what effects will be produced in humans by small amounts of strontium 90 carried for long periods of time. There is no direct experience with strontium 90 in humans under these conditions. We are therefore limited to extrapolations from animal studies and from effects of other radiation sources on humans. On consideration of the physical and chemical effects of strontium 90 radioactivity, there seems good reason to believe that no new type of effect will turn up, but again I believe this cannot be said with absolute certainty.

STRONTIUM 90 DOSE LEVELS AND INTERPRETATIONS IN TERMS OF NUMBER OF INDIVIDUALS AFFECTED

With the support of the AEC, data have been collected from any parts of the globe which permit a fairly accurate statement of the average dose of radiation from strontium 90. There is no important disagreement about this data per se. Here it should be stressed first of all that, in some areas, because of differences in fallout patterns, differences in the nature of the soil and differences in dietary habit, the dose of radiation from strontium 90 may be considerably higher than the average. However, accepting the average figure as a basis for discussion, what are the expected effects? Here, there is some disagreement, involving differing scientific opinion.

The principal effect of strontium 90 will probably be the production of bone cancer and leukemia. Although we cannot know the full effects of strontium 90 in humans until 20 years or more have passed, estimates of the number of new cases induced can be made, as already mentioned, by reference to animal experiments and to certain data on humans who have been exposed to radiation of other sorts.

That radiation can induce cancer is known. Animal experiments show that the number of induced tumors is directly related to the total amount of radiation given. It is true that these data are obtained with high doses of radiation and it is not certain that the results can be extrapolated to low doses of radiation. Such an extrapolation is, on the other hand, a reasonable one and results reported in a recent paper by E. B. Lewis (Science, May 17, 1957) strongly support the validity of such an extrapolation in the case of radiation-induced leukemia in man. Dr. Lewis' work suggests, in fact, that 5 to 10 percent of all present cases of leukemia are due to normal "background" radiation reaching the bones—cosmic rays, and natural radioactivity from our surroundings and from internal sources. If this is true for the cancerlike disease, leukemia, it is reasonable to assume that, for bone cancer as for leukemia, a fraction of present cases is due to normal background radiation. The total number of deaths due to bone cancer, in the United States, is only one-fifth of the number due to leukemia, so if we lump bone cancer and leukemia effects together, estimates of the production of these two diseases by radiation will not be far in error, even if we do not know with any accuracy what fraction of bone-cancer deaths is normally due to background radiation. We therefore assume that about 10 percent of the normally occurring cases of bone cancer as well as of leukemia are due to background radiation. (See p. 962.)

If natural background dose to the bone is responsible for 5 to 10 percent of normal leukemia and bone cancer, then even a small percentage increase over background would harm many individuals. The average bone dose of radiation from strontium 90 derived from tests already conducted will rise to 5 to 10 percent of natural background. The incidence of leukemia and bone cancer would consequently rise one-quarter to 1 percent. Since some 10 million individuals in the next generation would normally die of leukemia or bone cancer (estimate based on statistics for the United States), this one-quarter to 1 percent increase represents 25,000 to 100,000 individuals. Thus, although normally only about 1 in 150 or so of all deaths (statistics for United States) would be due to leukemia or bone cancer, an increase as small as one-quarter to 1 percent in this rate still represents many individuals.

It may be noted that these figures are consistent with a recent estimate made by the Radiation Hazards Committee of the British Atomic Scientists Association. That committee estimated that, subject to the assumption that even small radiation doses produce proportionate amounts of bone cancer, some 50,000 cases of bone cancer might be expected to develop as a result of nuclear tests already carried out.

A great deal of apparent disagreement on the dangers of fallout has probably been due simply to a difference in emphasis. The AEC has emphasized that the radiation from strontium 90 from tests so far will represent only a few percent increase over natural background radiation, on the average, and the AEC has further emphasized that this average increase in radiation due to strontium 90 is small compared to the additional radiation exposure many people receive as a result of living with a higher background radiation level than average, or as a result of medical X-rays. Relative to other sources of radiation, then, it is perfectly true that fallout radiation contributes, at the present level of testing, only a small additional increment. On the other hand, it can be stated that even a small percentage increase over natural background radiation is likely to harm a considerable number of individuals, as discussed above.

The likelihood that even a small percentage increase over background radiation will cause many deaths applies to radiation from other sources as well as to fallout radiation. It should be remarked that the very rapidly increasing awareness of the effects of radiation is already leading to greatly improved X-ray techniques.

THE EFFECT OF FLUCTUATIONS

The fact that fallout is not distributed with absolute uniformity among all the people of the world affects the evaluation of the fallout hazard in two important ways. First, as has been emphasized by many people, and particularly by Dr. William Neuman, if a "maximum permissible" level of fallout material, say of strontium 90, is agreed upon, then the world-average level should not be allowed to go beyond a fraction of it, or else an appreciable part of the world population would be subjected to more than the "maximum permissible" level.

Second, the detectability of fallout effects, which to a considerable extent determines the psychological impact of the effects, will be increased as a result of variations in the amount of fallout, in the diet, and in the nature of the soil. Some 50,000 individuals may develop leukemia and bone cancer from strontium 90 due to tests so far. If these 50,000 were fairly uniformly spread over the world, they would probably be undetectable among the 3 million or so "normal" cases of bone cancer and the 10 million or so "normal" cases of leukemia which would be present even if there had been no fallout. But in actual fact some world areas will suffer more heavily than others, due to diet and soil nature, and due to the nonuniform distribution of fallout. Although the world-average increase in leukemia or bone cancer, for 50,000 total cases due to fallout, would be only 1 in about 60 normally occurring cases of bone cancer, or 1 in about 500 normally occurring cases of leukemia, the relative increase in some areas might be as high as about 1 case for every normally occurring case of bone cancer. Even such a 100 percent effect, from tests so far, might be hard to detect, because the normal incidence of bone cancer is so low, and the number of people subjected to extreme levels is probably very limited.

IS THERE A DANGER FROM TEST FALLOUT?

The two principal effects of fallout appear to be the genetic effects from general gamma radiation, and the production of leukemia and bone cancer by strontium 90. Scientists are agreed that genetic effects are produced even by small amounts of radiation. With regard to somatic effects, such as cancer, a considerable body of scientific opinion holds, with some support from experimental data and with some basis in theory, that these, also, can be produced even by small doses of radiation. On the assumption that this is true, it can be estimated that the number of individuals likely to be directly harmed in the coming generation by strontium 90 will probably be greater than the number showing genetic effects in that generation—although, for a given amount of fallout, the genetic effects will persist for many generations and will eventually cause direct injury to a total number of persons comparable to that affected by strontium 90. In terms of the immediate impact, therefore. we can concentrate our attention on strontium 90. In regord to the genetic effect of fallout, Warren Weaver, vice president of the Rockefeller Foundation and Chairman of the National Academy of Sciences Committee on the Genetic Effects of Atomic Radiation, estimated before a Senate subcommittee on January 16 that radioactive fallout from nuclear weapons testing to date will account for some 6,000 of the 30 million "handicapped" babies to be born in the coming generation. In regard to the effects of strontium 90, estimates quoted previously indicate that some 50,000 individuals over the next 30 years may develop leukemia or bone cancer as a result of tests to date.

How much should one be concerned about fallout effects of this magnitude? This is not a question which can be answered on scientific grounds. Even if one accepts the interpretation of the data presented above as a basis for estimating the number of individuals who will show genetic or somatic effects as a result of the 50 megatons (millions of tons of TNT equivalent) fission yield of tests so far, there are a number of other factors that must be carefully weighed before final judgment can be reached on the significance of the hazard. Probably no absolute evaluation will be possible, but instead, the evaluation will have to be made relative to the problem of securing peace in the world and in relation to the moral problems involved. A discussion of some of these questions would take us out of the area at which this statement is directed.

but it does seem desirable to emphasize that three of the pertinent factors which must be considered are: (1) The uncertainties as to the number of individuals affected (the number may be smaller than 50,000, or larger), and the remaining uncertainties as to what all the effects of fallout radiation will be; (2) the size of the number 50,000 relative to the numbers of people harmed by other reducible effects; and (3) the fact that the fallout effects are global, involving citizens primarily of countries other than the testing countries.

The global effects of fallout (as opposed to the more local effects) come almost exclusively from explosions of large nuclear weapons; a single one of these can produce as much worldwide fallout as a thousand bombs of the size used at Hiroshima. Those who consider the further development of large nuclear weapons necessary for military security view the probable effects of fallout as a small addition to other hazards of day-to-day living. Those who consider that the further development of large nuclear weapons moves the world away from peace rather than toward it of course do not feel that the military desirability of such weapons justifies the probable fallout effects of tests. Finally, there is a third group who, while not certain whether the further development of large weapons is likely to be useful, feel that in view of the uncertainties as to the nature and magnitude of fallout effects, and in view of the international political impact that testing of large nuclear weapons produces in the involuntarily exposed majority of the world, the nuclear testing powers would be well advised to exercise strong restraint with regard to tests producing further significant amounts of fallout.

As new nations enter the nuclear testing program, it can be expected that they will be interested in testing bomb types which produce a great deal of fallout. There are two dominant reasons for this: First, about the most economical way possible to increase the yield of a large bomb is to use an outer shell of natural uranium. This leads to an inexpensive large energy release, but also to a large release of fission products—the worst kind of fallout. Second, a large amount of fallout increases the devastating power of a nuclear bomb. The addition of a shell of natural uranium to a large thermonuclear bomb can increase the devastating fallout to a very much greater degree, for example, than the addition of cobalt to make a "cobalt bomb," and moreover can at the same time increase the energy release by a large amount, which a cobalt shell will not do.

Although the United States appears to have turned its efforts to desiging nuclear weapons which produce less fallout, the U. S. S. R. does not appear to have followed suit as yet. While the United States Pacific tests of last spring did not add very appreciably to the strontium 90 in this country, the first 4 Russian test explosions of last fall resulted in an increase of about one-third in the strontium 90 concentration in United States soil, within a period of a few weeks. Since that time, the U. S. S. R. has set off at least 8 additional nuclear explosions (as of May 15). No information of any precision has as yet been released on the size of these explosions and on the amount of radiactive fallout resulting from them.

THE AMOUNT OF TESTING WHICH CAN BE "TOLERATED"

It is not practical to speculate here on what new kind of fallout radiation might be produced by new types of nuclear weapons. Consequently the "tolerable" level of testing will be discussed in terms of the kinds of weapone which have already been exploded. As discussed previously, attention will be concentrated on the effects of strontium 90.

Official evaluations of the strontium 90 hazard have generally been given in terms of a "maximum permissible concentration" (MPC). The use of such a term is unfortunate, since it implies that the immediate and long-term effects of small amounts of strontium 90 in human bones are known with precision. They are not. Furthermore, it has been noted by many specialists that a "maximum permissible" dose is not necessarily a safe dose. It is possible to estimate form available data that, if a large number of people are given a "permissible" dose, of one-tenth microcurie of strontium 90, then it is likely that about one in a thousand will develop bone cancer in his lifetime. (This estimate follows directly from the results of the British Atomic Scientists Association study of strontium 90 referred to above.)

The uncertainty in the specification of a "permissible" level is indicated by the fact that the AEC has recently felt it advisable to revise downwards the strontium 90 level considered "permissible," to one-tenth of the value formerly used—namely, to one-tenth microcurie for the "standard" man. This has

brought the AEC "permissible" level into agreement with that recommended for "large populations" by the International Commission on Radiological Protection. No recommendation has been given for the case that the entire world population is exposed; for this case, there is good reason to take the "acceptable" value as being still smaller.

Strontium 90 decays relatively slowly (half life of 28 years), and so the effects of amounts produced within a span of only a few years are cumulative. The amount of strontium 90 distributed over the world in fallout is proportional to total fission yield for a nuclear explosion. How many megatons (millions of tons of TNT equivalent) of fission yield can we "tolerate?" No simple answer can be given to this question.

As discussed previously, the setting of a "tolerance" level is arbitrary. It can reasonably be expected that for leukemia and bone cancer due to strontium 90, just as for genetic effects, even small amounts of radiation will produce proportional effects. According to the estimates given previously, a worldwide average strontium 90 level equal to the (new) "permissible" level would be likely to produce several million cases of leukemia and bone cancer. (A worldwide average level equal to the old "permissible" level would correspondingly be likely to produce several tens of millions of cases of leukemia and bone cancer.) On the basis of these estimates, one would hardly be willing to permit the world-average strontium 90 level to come at all near the "permissible" level.

This points up the urgency of obtaining a more accurate evaluation of the level of strontium 90 which can produce injurious effects. It can be expected that it will be some time before such information can be obtained, because the full effects of small doses will probably appear only after 10 or 20 years, or more.

This discussion also points up the fact that use of the term "maximum permissible level" does not give an accurate impression either of the uncertainties involved or of the fact that, if the world-average strontium 90 level were to become equal to the (new) "permissible" level, then the damage likely to be produced is measured in millions of cases of bone cancer and leukemia, and is hardly likely to be "permissible." It would be better to express the magnitude of fallout radiation in arbitrary units—say, in "strontium units"—or else relative to the average magnitude of background radiation.

Let us return to the question of how many megatons of fission yield we can tolerate. It is frequently useful to use the magnitude of an existing hazard as a yardstick for evaluating a contemplated hazard. In this case, we may use as a yardstick the amount of strontium 90 already released by tests to date. By such a yardstick, it could reasonably be argued that an increase of, say, 1 part in 1,000 in the amount of strontium 90 already distributed globally would hardly be considered catastrophic. An increase of that amount would be produced by some 50 kilotons (thousand tons of TNT equivalent) of fission yield—2 or 3 of the small bombs used to destroy Hiroshima.

The explosion of megaton-range weapons may or may not produce large amounts of fallout, depending on the bomb design—in particular, depending on whether a large part of the energy release comes from fission. It would take only a few bombs of a type releasing some 10 megatons of fission energy to double the total global fallout now existing. It is clear that so far as radiation hazard is concerned, for bombs of the types which have been tested so far, attention can be confined to the large bombs. As to the question of how much we should be concerned over a doubling, say, of the fallout produced so far, that is a matter into which many complex factors enter, as discussed previously, and no answer can be given on scientific grounds alone.

FALLOUT IN WAR

Although there is much room for disagreement on evalution of the available data as to the results of fallout from tests, there is no disagreement as to the utter catastrophe that would result from a full-scale nuclear war. Hundreds of millions of people would be killed outright by blast, fire, and radiation, hundreds of millions more would die from the later effects of radiation injury, further comparable numbers in succeeding generations would suffer from genetic effects resulting from the radiation, and large parts of the devastated countries would be not only destroyed but made uninhabitable for extended periods.

REAPPRAISAL OF FALLOUT PROBLEMS

The AEC is to be highly commended for the detailed measurements it has made on fallout, and for the steady release of the results of these measurements.

However, the AEC has the dual responsibility of conducting a weapons development program and of evaluating the fallout hazard. It can readily be seen that decisions felt to be necessary in one area might conflict with and unduly influence decisions in the other. Because of these conflicting responsibilities, it may legitimately be questioned whether both functions belong in the same agency.

The suggestion has been made that an independent group of qualified scientists be appointed to take over the study and evaluation of fallout hazard and other radiation problems as well. In 1955, the National Academy of Sciences appointed a group to conduct such a study. The report submitted by that group was prepared over a year ago. Since that time, many new data have become available and many highly qualified specialists have expressed criticisms of the AEC's treatment of fallout problems. It is very desirable that appraisal of these problems be brought up to date. It can be expected that a group chosen to include representation of differing points of view can arrive at agreement on an interpretation of the data which can serve as an authoritative basis for policy decisions regarding future weapons testing.

CONCLUDING REMARKS

We are at the present time forced into the difficult position of having to make decisions on a problem that we do not fully understand. The data on hand, however, do tell us this much: The fallout radiation from past tests will constitute over the next few decades a small percentage increase over background radiation. It is estimated that even this small percentage increase will cause genetic changes affecting some tens of thousands of individuals over a number of generations, and will probably also produce leukemia or bone cancer in a comparable number of individuals over the next few decades. The fallout effects will increase with the amount of fission yield in future tests. Each small explosion will contribute only a small addition to the fallout radiation already produced; each large explosion can contribute an appreciable addition.

It should be emphasized that the effects of nuclear tests are thousands of times smaller than the effects which would result from a nuclear war. While there is no disagreement that nuclear war would be a disaster which we cannot afford, there is disagreement on the best means of avoiding such a war, and some of that disagreement seems to have spilled over into the area of evaluation of the fallout hazard.

An objective scientific evaluation of the radiation hazard from fallout can be, and should be, made independently of any military or policy considerations. The extensive information being compiled at these hearings will be of considerable help in arriving at such an evaluation.

Dr. SELOVE. On the question of how much testing can be tolerated, you have had testimony here as to a possible permissible testing level of a number of megatons per year. I would like to emphasize that in arriving at a permissible level the question of whether or not there is a threshold is a crucially important one. For those effects for which there is no threshold, for which effects are produced by even small amounts of radiation, then certainly without question from anyone effects are produced by even the smallest amount of testing and if one wants to continue a testing program it can only be on the basis of balancing the presumed advantages from testing against the certain disadvantages in terms of individuals affected.

With regard to the specification of a permissible level, I think it should be said that the use of the term "maximum permissible concentration" is rather unfortunate, especially with respect to strontium 90, since this term implies that the immediate and long-term effects of small amounts of strontium 90 in human bones are known with precision. They are not known with precision.

Furthermore, it has been noted by many specialists that a "maximum permissible" dose is not necessarily a safe dose. It is possible to estimate from available data that if a large number of people are given a permissible dose such as is now used for the population and

if the effects of strontium 90 are proportional to the dose, then it is likely that about one in a thousand will develop bone cancer in his lifetime.

Senator ANDERSON. Does that mean one additional person?

Dr. SELOVE. One in a thousand of all individuals. One in a thousand normally die of bone cancer. I am saying it can be estimated from the numbers which have been given to this committee, that if the entire world population were to receive what is now called a maximum permissible dose of strontium 90 for the population, that is 10 times less than the level prescribed for occupational exposure, then it can be estimated that one in a thousand of all the people in the world would develop bone cancer. That means that several million cases of bone cancer and leukemia would be developed. On this basis one would hardly be willing to let the world level of strontium 90 to come to the permissible level.

Senator ANDERSON. I am sorry I did not get the question clearly. You said a certain number would develop bone cancer independent of the fallout?

Dr. SELOVE. Yes.

Senator ANDERSON. Did you say an additional number would develop it?

Dr. SELOVE. Yes.

Senator ANDERSON. One out of a thousand additionally would develop it.

Dr. SELOVE. That is correct. In other words, even without fallout, during the next 30 years when some half of the present world population is dying, some 3 million cases of bone cancer would normally develop. Some 10 million cases of leukemia would normally develop. If the world were to receive a maximum permissible dose of strontium 90 it can be estimated that these normal effects might be almost doubled.

On that basis we would hardly be willing to have a world average level equal to the permissible level. This rests on the crucial question of whether the effects of small doses of strontium 90 are visible or whether there is threshold. This point you have heard much discussion on. I think you have seen by now that there is not at present sufficient data to know whether there is or is not a threshold behavior.

Senator ANDERSON. Would I be safe in concluding that most of the geneticists believe that there was not a threshold?

Dr. SELOVE. I think that would be a fair interpretation.

Representative COLE. No threshold as far as genetic effects are concerned?

Dr. SELOVE. There is complete agreement on that question. Comparable numbers of individuals will be affected genetically to those affected by strontium. It is true the genetic effects are spread over a large number of generations; so in the coming generation, for a given amount of fallout, the number of individuals who show genetic effects may be 10 times smaller than the number who will show the effects of strontium 90, if they show them at all.

Therefore, as far as the immediate impact of the fallout is concerned I would say we can confine our attention to strontium 90.

The AEC has made very fully——

Representative COLE. On that last statement, Doctor, does that mean that in your opinion we should be considerably more concerned about the effect of strontium 90 than be concerned with the genetic effect of fallout?

Dr. SELOVE. No. I think according to the estimates one can make from the present limited data, about comparable number of individuals will be affected genetically and by strontium 90.

However, during the next 30 years one can estimate that some 6,000 babies will show serious genetic effects from fallout so far, whereas some 50,000 individuals may develop leukemia or bone cancer from fallout so far.

Representative COLE. Of what population?

Dr. SELOVE. The world population.

Chairman DURHAM. That is based on the amount of strontium at the present time in the stratosphere.

Dr. SELOVE. From tests so far. Most of the strontium 90 produced is now on the ground.

The AEC has made very fully available its measurements on fallout, and it should be commended for this. However, the AEC has the dual responsibility of conducting a weapons-development program and of evaluating the fallout hazard. This is a very difficult position for anyone to be placed in. I would not want the job. It can readily be seen that decisions felt to be necessary in one area might conflict and unduly influence decisions in the other. Because of these conflicting responsibilities it may legitimately be questioned whether both functions belong in the same agency.

The National Academy of Sciences has made an independent study of these problems with a group appointed in 1955. The report prepared by that group was prepared about a year and a half ago. Since that time, many new data have become available and many highly qualified specialists have expressed criticism of the AEC's treatment of fallout problems. I think it is very desirable that an appraisal of these problems be brought up to date. It can be expected that a group chosen to include representation of different points of view can at least arrive at agreement on what can be positively concluded from the available data.

I would like to summarize that we are at the present time forced into the position of having to make decisions on a problem that we do not fully understand. That data on hand, however, do tell us this much: The fallout radiation from past tests will constitute over the next few decades a small percentage increase over background radiation. It is estimated that even this small percentage increase will cause genetic changes affecting some tens of thousands of individuals over a number of generations, and will probably also produce leukemia or bone cancer in a comparable number of individuals over the next few decades. The fallout effects will increase with the amount of fission yield in future tests. Each small explosion will contribute only a small addition to the fallout radiation aready produced. Each large explosion can contribute an appreciable addition.

It should be emphasized that the effects of nuclear tests are thousands of times smaller than the effects which would result from a nuclear war. While there is no disagreement that nuclear war would be a disaster which we cannot afford, there is disagreement on the best

means of avoiding such a war, and some of that disagreement seems to have spilled over into the area of evaluation of the fallout hazard.

An objective scientific evaluation of the radiation hazard from fallout can be, and should be, made independently of any military or policy considerations. The extensive information being compiled at these hearings will be of considerable help in arriving at such an evaluation.

Senator ANDERSON. Thank you, Doctor. I do want to assure you that this committee has been trying to make some sort of objective scientific evaluation of it.

Dr. SELOVE. I want to commend it for its effectiveness in bringing out such a vast amount of data in a way which will be very understandable to very many people in such a short time.

Senator ANDERSON. We appreciate very much the contribution which the scientists have made and are making to this, you included. I am very sorry that you had to wait to the end of a long day for your paper.

Dr. SELOVE. I am sorry you had to sit through it.

Senator ANDERSON. We are happy to do it.

The committee will meet tomorrow in the House caucus room at 10 o'clock.

(Thereupon, at 5 p. m., Wednesday, June 5, 1957, the committee recessed, to reconvene at 10 a. m., Thursday, June 6, 1957, in the House caucus room.)

THE NATURE OF RADIOACTIVE FALLOUT AND ITS EFFECTS ON MAN

THURSDAY, JUNE 6, 1957

CONGRESS OF THE UNITED STATES,
SPECIAL SUBCOMMITTEE ON RADIATION
OF THE JOINT COMMITTEE ON ATOMIC ENERGY,
Washington, D. C.

The special subcommittee met, pursuant to recess, at 10:05 a. m., in the caucus room, Old House Office Building, Hon. Chet Holifield, chairman of the subcommittee, presiding.

Present: Representatives Holifield, Durham (chairman of the Joint Committee), Price, Cole, Van Zandt, Jenkins; Senators Anderson and Bricker.

Also present: Professional staff members: James T. Ramey, executive director; George E. Brown, Jr., Hal Hollister, staff technical adviser, and Paul C. Tompkins, consultant.

Representative HOLIFIELD. The subcommittee will be in order.

We have planned to start the meeting this morning with a discussion on the present state of affairs, and we have invited Dr. Libby, Dr. Selove, Dr. Neuman, Dr. Machta, Dr. Crow, Dr. Brues, and Mr. Eisenbud to take part in this seminar. I understand Dr. Shields Warren is here, and we will be delighted to have you come up.

Will you gentlemen come forward to the table?

Mr. Hollister will start off the seminar with a statement or question.

DISCUSSION BY DRS. WILLARD F. LIBBY, WALTER SELOVE, WILLIAM F. NEUMAN, LESTER MACHTA, JAMES F. CROW, AUSTIN BRUES, MERRIL EISENBUD, SHIELDS WARREN, CHARLES L. DUNHAM, BENTLEY GLASS, AND WRIGHT LANGHAM

Mr. HOLLISTER. Mr. Chairman, I would like to suggest, because of the long and tiring day we had yesterday, and because Dr. Selove has made special arrangements to be with us this morning for about an hour, that he be given about 10 or 15 minutes to summarize very quickly the points that he was making yesterday afternoon.

Representative HOLIFIELD. Will you do that, Dr. Selove, in order that we may regain the points in your testimony. Also I understand you have to leave at 11 o'clock.

Dr. SELOVE. Yes.

Representative HOLIFIELD. So we will let you start off.

Dr. SELOVE. Thank you.

This discussion yesterday and this morning is intended to provide a summary discussion of the interrelationships and implications on pol-

icy of fallout matters. I would just like to simply itemize the principal points that I would like to make at this time.

First, I think it has been brought out clearly before this committee that there is some effect from any amount of radiation. There is complete agreement among geneticists and others who have studied the problem that genetic effects are produced even by very small amounts of radiation. Of course, with extremely small amounts, there are correspondingly small effects.

But the major point is there is no safe level for genetic effects in the sense of the existence of a level below which no effects would occur. There is no such level.

As to the somatic effects, and perhaps the ones that have received the most attention are the production of leukemia and bone cancer by strontium 90, there is not sufficient scientific evidence at present to determine whether or not there is a safe level for such effects.

I believe it is fair to say, as I said yesterday, that on the basis of the available data, the interpretation that effects are produced even by small amounts of strontium 90 seems to be at least as reasonable as the interpretation that they are not.

The second major point I would like to make is that I believe the term "permissible level" is an unfortunate one to use in discussing fallout effects. These effects, to be sure, may be very small on a percentage basis. At the same time they may involve many individuals. I think "permissible level" is a term which is generally understood to mean a level not such that there is no risk at all, but a level which is taken to be acceptable by those subjected to the hazard in return for some presumed benefit.

Now this is true, for example, in the case of X-ray exposure where there is certainly some genetic effect.

Representative HOLIFIELD. May I interrupt you just a moment? I understand Dr. Glass is in the audience. Dr. Glass, we have one empty chair up here. Would you join us?

Dr. GLASS. Yes.

Representative HOLIFIELD. Continue, Dr. Selove.

Dr. SELOVE. To continue, then, in the case of X-rays, for example, the permissible level has been established——

Senator ANDERSON. Just a second. I would hope if we are going to fill this extra chair, we would add another one and ask Dr. Dunham to come up.

Representative HOLIFIELD. Dr. Dunham, we can find a chair for you, too.

Of course, getting this many here is not to make it mandatory that each one of you take 20 minutes. It is only if you have something of real importance to add that you feel like you should add. Otherwise, it might become unmanageable. But we want to show you the courtesy of an opportunity in case you do wish to speak.

Go ahead, Dr. Selove. Excuse me.

Dr. SELOVE. I would like to reemphasize that a permissible level should be understood to be a level which the people who are subjected to it, or their representatives, have decided is an acceptable level in view of the advantages associated with whatever hazards we are concerned with.

In the case of radioactive fallout, although the effects represent a very small percentage of similar effects occurring normally, in view

of the worldwide concern over this effect, it is not correct to speak of permissible level meaning no risk. It should be understood just what is meant by permissible level.

Senator ANDERSON. In other words, you think there ought to be a balance. You weigh the dangers?

Dr. SELOVE. Against the advantages. Ordinarily, in the case of X-rays, for example, a doctor and his patient decide together—actually, of course, the doctor decides— whether the advantages to be obtained from an X-ray are worth the disadvantages, which are relatively small from an individual X-ray as in the case of radioactive fallout. I do not mean to draw any conclusions here. I just wanted to point out that the peoples of the world are subjected to the radioactive fallout produced by tests from all powers, and they may not be quite so convinced that they are receiving advantages to compensate for the disadvantages. In that sense, the term "permissible," I think, is a misnomer.

The third point I would like to make concerns the size of the effects. This is a very complex question. One simply cannot describe it with a single sentence, or even a pair of sentences. One has to take many aspects of the problem to obtain a balanced view of what the size of the effects is.

I would be glad later to make some further comments on this, but at the moment let me make some very short ones.

Effects from fallout from tests so far are small compared to the effects of other radiation sources to which people always have been exposed, and are currently exposed. The effects are so small they may be undetectable. However, the numbers still constitute many individuals affected even if we just concern ourselves with genetic effects. If we concern ourselves with the possibility of somatic effects in addition, this adds some number of individuals.

The effects are global. They are roughly calculable. They can be calculated by scientists of other countries as well as by scientists of our own.

The next point I would like to make concerns the uncertainties, first, in the magnitude of the effects.

The numbers presented to this committee represent, in general, best estimates as to how many individuals will be affected. No one is in a position to say how accurate these estimates are. I would think it is believed that the estimates that are given you are accurate within 10 times. The true numbers may be 10 times larger, and may be 10 times smaller.

There are uncertainties also in the nature of the effects produced by radiation, by fallout radiation in particular. I do not mean to hint here that there are going to be some serious effects turning up that we do not suspect as yet. I just want to repeat what many witnesses have said—that because many of these things are new to the human race, it is likely to be a generation, until people have carried these radioactive materials in them all their lives, before we really know what the effects are.

It has to be pointed out also that we have good reason to believe we know what the principal effects will be.

Next I want to point out that, so far as radioactive fallout is concerned, one should make a clear distinction between the effects produced by large bombs and the effects produced by small bombs. A

large bomb can produce on the order of a thousand times as much fallout as a small bomb. And if one goes into the question of test bans, then one should make a clear distinction between the effects of small weapons and the effects of large weapons. It is actually, of course, the total amount of fission products released that is important.

Next I want to reemphasize what has been brought out here at these hearings, and a point I tried particularly to make here yesterday, that it can be strongly expected that new nations which enter the testing program will be very interested in testing bomb types which produce a great deal of fallout. There are strong reasons why they will want to do so.

We have seen in the tests of Russia last fall that in just a few explosions, the strontium 90 in this country was increased by one-third, in the soil of this country. This does not represent an increase on a worldwide basis, because of the question of uniformity of distribution and storage in the stratosphere, but the level of the soil in this country was increased by that amount by just a few explosions.

Representative HOLIFIELD. Would you hazard a guess at this time—I do not like to say "guess." Would you hazard an opinion that, in view of the fact the Soviets have tested large bombs on their own territory, there may be an appreciably greater extent of strontium deposit from the local fallout on their own territory?

Dr. SELOVE. In Russia?

Representative HOLIFIELD. In ratio to the stratospheric fallout which has occurred here and raised our level one-third.

Dr. SELOVE. I think probably many of us saw in the Washington Post yesterday morning a Russian report indicating that strontium 90 levels, at least in some areas of Russia, were twice as high as the highest levels in this country.

Senator ANDERSON. Which might explain the sudden Russian interest in stopping nuclear tests and preventing nuclear warfare.

Dr. SELOVE. The decision concerning balance of factors in deciding whether or not to try to obtain an agreement for a test ban—these decisions, of course, involve many other factors other than radiation hazards. I am trying to restrict myself here to that one.

I would next like to reemphasize, as many witnesses here have done, that the effect of a nuclear war would be enormously greater than the effects of fallout from tests.

Again, this remark on this matter: In balancing various factors involved in decisions about test bans, one really has to include such things as the question of whether continued weapons testing will actually help us to avoid a nuclear war. No one disagrees that a nuclear war would be just utter devastation. We have to avoid it. There is considerable disagreement as to the best way to avoid it, but there is no reason for that disagreement to extend into the area of evaluation of radioactive fallout hazards. I think we can and should make that an objective evaluation.

Next, as to the evaluation of fallout hazards, this is anything which has been carried out by the Atomic Energy Commission, by the National Academy of Sciences in an independent study last year, by the British Medical Council, and by various other less formally organized groups.

I think with regard to the Atomic Energy Commission, as I stated yesterday, there is likely to be considerable conflict in the dual re-

sponsibility which the Commission has for evaluating radiation hazards and for concerning itself with the weapons development program of this country. It is a very unfortunate and burdensome problem. I do not think any of us would want to be saddled with it.

I think it can legitimately be questioned whether these two functions—the evaluation of radiation hazards, and concern with the weapons development program—belong in the same agency.

As for the question of independent studies of fallout problems, I would like to make my next point the fact that the National Academy of Sciences report, which is still referred to up to the present time as the latest authoritative report in this country, is seriously out of date. That report was prepared about a year and a half ago. It was issued about a year ago.

The National Academy has, of course, been continuing to study these problems. I think further reports from them at this time would be very much in order nad very welcome. I am sure they are working on them. I think it might be of interest to hear how soon one can expect such further reports to appear.

Finally, I would like to repeat a conclusion of the radiation hazards committee of the Federation of American Scientists, a report from which committee I am inserting in the record. It contains, I think, several numbers of interest.

It is a principal conclusion of that committee, representing some eight people who have studied the radiation hazards problem from fallout quite a long time as such committees go, I think—it is a principal conclusion of theirs that a decision on testing nuclear weapons cannot be based purely on the scientific problems involved, cannot be based purely on radiation hazards, but must involve primarily moral questions, and questions of the effect on international relations and international affairs of our decision on a test ban.

I would like to summarize, then, by saying that the view I have tried to present of fallout problems I think is neither an alarming one nor a calming one. The problem simply does not reduce to such simple terms as those. It is a very complex problem. I do not think a balanced study of it delivers so spectacular a conclusion as that the problem is either of alarming proportions or of negligible proportions. It deserves a lot of serious study. You gentlemen have given it much of that here, and I believe it will be extremely useful.

Representative HOLIFIELD. Thank you very much, Doctor.

Dr. Libby, do you have any comment?

Dr. LIBBY. I find myself in agreement with much of what Dr. Selove said. We certainly must continue to take this problem very seriously, and study it.

In reading the testimony before the committee, I am impressed with the disparity in our knowledge of the biological effects as compared to our knowledge of the physical facts about fallout, which leads me to suggest that we ought to try harder to get some answers to the questions of the genetics, the effects of low radiation doses taken over long periods of time in causing cancer and leukemia, from experimental data.

But we certainly ought to continue the program.

I certainly agree with Dr. Selove this is not a negligible factor. We must take it seriously.

My testimony yesterday shows that I agree with him that nonscientific considerations are involved in the final decision.

Chairman DURHAM. Dr. Libby, I think you are in general agreement that the biological studies should be increased. Does the Commission have facilities available at the present time—and when I speak of facilities, I mean brains and everything else connected—to step this up in the biological field?

Dr. LIBBY. I believe so, but I would like to ask Dr. Dunham to answer that question.

Dr. DUNHAM. Mr. Chairman, we do have facilities. We do have some manpower. This can be stepped up. It cannot be stepped up suddenly by a matter of several orders of magnitude either within the Commission or without the Commission, because there still is, as you hinted in the way you put the question, a limited number of available competent scientists to work in this field.

This is a very real problem, because, if the work is not done competently, it will cause more confusion.

But there definitely could be a step-up in the program over the next few years. There is no question about it.

Chairman DURHAM. Dr. Dunham, since you are in charge of this primarily, do you have funds available, or will you have with what you requested this year from the Congress?

Dr. DUNHAM. We have, as the Congress knows, in our 1958 budget an increase in the request. As you know, these budgets are prepared nearly a year and a half in advance of the coming before the Congress for appropriations.

The cost of scientific living, I mean the cost of doing experiments, is constantly going up. So I would be less than candid if I said that what seemed like a reasonable budget in May of 1956, looks so reasonable today.

Chairman DURHAM. Doctor, since you made that statement, I wish you would send up to the committee your recommendation on it as early as you can. It will not be long before Congress adjourns here, and I think this committee feels like, of course, you should have whatever funds are necessary to carry on the investigation in the biological field.

Senator ANDERSON. May I just ask there: Dr. Selove suggested that the report of the National Academy of Sciences is out of date, and he wanted to know when the next report might be ready. Is there anyone here who can give us any indication of when the new data will be studied and a report made on it, since he says the old report is seriously out of date?

Dr. WARREN. If I might comment on that, Mr. Chairman.

Senator ANDERSON (presiding). Very well.

Dr. WARREN. There is a continuing study made by the various groups assigned by the National Academy of Sciences to all this program. At the present time there are no available facts which would warrant a change to a significant degree in the reports for the pathological effects, the somatic effects. I think Dr. Glass would probably agree with me that there is no very large increment of data in the genetics field.

Senator ANDERSON. The testimony of the geneticists would not indicate that, certainly, would it?

Dr. WARREN. I would rather have Dr. Glass comment on that particular point.

Dr. GLASS. I will later.

Dr. WARREN. Both of the committees have been asked by the president of National Academy of Sciences to meet periodically to keep in close touch with new data as it becomes available, and to issue reports as often as it seems wise to them.

I would say that at the present time, so far as the report on the pathological effects are concerned, that there are no points that as yet are sufficiently well established to warrant a significant change in that report as it stands.

Senator ANDERSON. Now, Dr. Selove, if you think the report is out of date, and Dr. Warren says there are now new facts that have been discovered to change it in any degree, could you give us briefly the basis for your statement?

I rather got the impression there were some new facts, and I thought these scientists had been presenting them. I judge from Dr. Warren's statement, as far as the group, they are going to stand pat on what they put out a year and a half ago.

What do you think about it?

Dr. SELOVE. Dr. Warren is, of course, the chairman of the pathology section of the National Academy of Sciences' study, and is certainly in a position to speak for that group. Some 8 months ago, I communicated with the president of the National Academy, Dr. Bronk, asking whether, in view of the renewed attention that some of the fallout effects were receiving, particularly in view of the attention to strontium 90, whether the National Academy group had any expectation of producing a new report at any time in the near future. And he replied that the matter was under consideration; that a certain number of members of the study group had asked for a renewed study of this problem; and he expressed agreement with the idea that the problem needed more attention, it being understood, of course, that the radiation committees, the subcommittees of the National Academy, have been organized on a continuing basis.

I think there may be some statements in the pathology committee's report which perhaps, in view of the testimony that has been presented to this committee here, might not represent a sort of average view or balanced view of the various notions that specialists in the field now have.

I recall at the moment, not having the report here with me, only one. I think there is a discussion, in the report of the pathology committee, of an unequivocally safe level. I think, in view of the testimony that has been presented here, it is clear that the scientific evidence presently available is not sufficient to say whether or not there is a threshhold level, a level which would be absolutely safe. If the interpretation presented by many specialists in the field that even small doses of strontium 90 can produce bone cancer and leukemia is correct, then I think this point, which I tried to make earlier, that there would be no safe dose at all, is a point which might well be expressed so as to revise that particular statement.

Senator ANDERSON. I know you have to catch a plane, and a member of the staff, Mr. Hollister, has some questions to direct to you. I guess we had better proceed with those.

Representative COLE. If I may come back in where Mr. Durham was discussing with Dr. Dunham the possibility of stepping up this inquiry in the field of biological aspects.

The impression has been created, I fear, that in this field there has been a party line, what might be called a party-line concept of disclosure of the consequences of radiation, in that the Commission has laid out a policy, and other people in the laboratories have tried to find answers which would support that policy.

On the other hand, to disprove that the witnesses, many of them, indicated a large degree of independence in their research, that there is no control by the Commission with respect to their areas of inquiry or conclusions.

Now my question of Dr. Dunham is: In the event that, Dr. Dunham, you do find there is opportunity for stepping up this inquiry, do you see any need or opportunity for enlarging that aspect of independent research beyond what it is now?

Dr. DUNHAM. I do not feel that there is a need to enlarge the independent aspects, because essentially there is a total independence, as Dr. Brues will, I am sure, testify later today when he discusses the research program.

Representative COLE. You mean the present program is essentially completely independent?

Dr. DUNHAM. That is correct, as far as directing or limiting in any way what the scientists, either in the Atomic Energy Commission national laboratories, the major projects, are doing, or university scientists which we support through contracts with our universities.

Senator ANDERSON. Mr. Hollister.

Mr. HOLLISTER. Dr. Selove, I wonder if you would be willing to state for the record, either speaking for yourself or for the Federation, what you feel are the essential differences and similarities in the conclusions of the National Academy report and the British Medical Council report, as far as such questions as genetic effects, MPC, and so on, are concerned?

Dr. SELOVE. As far as what?

Mr. HOLLISTER. As far as such questions as genetic effects, MPC, and so on, are concerned.

Dr. SELOVE. I have to speak for myself, although I believe what I will say reflects the views of the Radiation Hazards Committee. Nothing I say reflects the views of the Federation of American Scientists. This is, of course, a technical matter, and the federation has no policy on such a matter.

I believe the British Medical Council report, which is a report by an organization in Britain separate from the organization which has to do with weapons-testing decisions, just as the National Academy here is, of course, separate from the AEC—I think that report, in my opinion, tends to be perhaps slightly more conservative than the National Academy report.

I recall, for example, that in the British Medical Council report it was suggested that, if the general level of strontium 90 in the population should show signs of increasing greatly beyond one one-hundredth of the occupational permissible concentration, that it would indicate the necessity for a strong reconsideration of the problem.

I think that was a somewhat lower level at which the British Medical Council expressed concern than the level suggested in the National Academy report.

Senator ANDERSON. How much would that be in sunshine units, Doctor?

Dr. SELOVE. That would be 10 sunshine units. The level in the world from tests so far is expected to rise to 2 to 3 sunshine units on the average.

Representative COLE. Mr. Chairman, I wonder if you would mind just experimenting for a moment to see if we cannot do better with these microphones cut off, and everybody speaking up a little louder.

(Discussion off the record.)

Dr. SELOVE. The British Medical Council report, I believe, took a slightly more conservative tone than the report of the National Academy of Sciences. The report of the National Academy group was also conservative, let me hasten to say.

Representative COLE. Speak up so that the audience hears.

Dr. SELOVE. I am not sure I can. I am trying to speak to the committee. I am not sure I can speak to the committee and have the audience hear it at the same time.

I believe in the British Medical Council report another point of difference which occurs to me, with the conclusions that one would draw from reading the National Academy report—another point of difference was that with regard to the possibility that the effects of even small doses of strontium 90 would be felt in terms of the production of a certain amount of bone cancer and leukemia, this possibility was brought out somewhat. I do not recall whether that possibility was discussed in the National Academy report. Perhaps Dr. Warren can answer.

Dr. WARREN. I think probably Dr. Brues can answer this better than I, because his particular group of scientists were the ones who had special knowledge with regard to strontium and the internal emitters.

Dr. BRUES. I am sorry I do not have a copy of the report with me at the present time. I know that the possibility was very seriously considered. I know that it is in some way mentioned in the report, but I am sorry that I cannot say exactly how.

I think that the report looked at the problem from the standpoint of the fact that some radiation is present, that therefore if——

Senator ANDERSON. Is this it [indicating document]?

Dr. BRUES. I am sorry. I am afraid this is not the one which contains the subcommittee report. Perhaps the committee would like to entertain another question while I consult the report.

Dr. NEUMAN. I wonder if it would be appropriate, since we are going to find out what was intended to be meant in the report, to consider what a very interested reader got out of the report, and have that question while we are waiting?

Senator ANDERSON. We are just trying to get through Mr. Hollister's last question before Dr. Selove will have to leave for his plane.

Go ahead.

Dr. NEUMAN. I came away with a little less drastic view than Dr. Selove. I think that the British report expressed this figure of 10 sunshine units essentially as a worry dose—recognizing that, if the strontium levels in the population rose, that we should seriously recon-

sider the matter of MPCs. This is only a suggestion. The British report does not really differ from the National Academy's position.

In reading the NAS report, I do not know, of course, what was intended, but I came away with the feeling that there was a division of opinion in the committee, and that this report indicated some people's feeling that the threshold dose did exist, (the MPC then might be really an MPC) while others did not accept the concept of threshold.

I think there were areas of disagreement, and that a compromise was reached. I hope that, before we leave, this group might consider the matter of the MPC. This finally (the MPC) is the operational number that you use in translating these discussions into real action.

Senator ANDERSON. Thank you, Dr. Neuman.

Dr. SELOVE. I would like to toss out again at that point that I believe, on the basis of available data, the interpretation that small doses will produce effects of strontium 90 is at least as reasonable as the interpretation that they will not, even though no one is in a position to say certainly. However, if one takes the conservative view and assumes that small doses may produce effects until proven otherwise, one is then in a position to estimate roughly how many individuals will be affected by a given amount of strontium 90. And the dose which has been specified as permissible for the population or for a large part of the population, namely a hundred sunshine units, such a dose can be estimated to produce in the world several million cases of leukemia and bone cancer, if that becomes the average world level.

I think it would be generally agreed that, if the occupational dose, which is ten times that level, if the entire world population were subjected to an occupational permissible level, there would be several tens of millions of cases of leukemia and bone cancer, on the assumption that small doses do produce effects.

The difference between the occupational level, and the population level is a matter about which a question was put yesterday, and I think it should be pointed out, in the answer to that question, that the principal reason which the International Commission on Radiological Protection has for specifying a smaller level as a permissible level for the population—the principal reason is the uncertainty that exists as to just what the effects will be.

The International Commission on Radiological Protection has tried to arrive at a level which, on the basis of the limited data available, it thinks will not injure a large percentage of people exposed to that level.

If one considers exposing the entire world population to that level, then, in view of the uncertainties, one simply has to recommend a lower level. That is the basis of the difference.

I am just pointing out that, on the basis of estimates that can be made from presently available data, even the lower population permissible level, if the entire world is subjected to it, could be expected to produce several million cases of leukemia and bone cancer. So we would hardly want to approach that level until we know more surely whether or not small doses do produce effects.

Senator ANDERSON. Do you have another question, Mr. Hollister?

Mr. HOLLISTER. I would like to ask Dr. Selove, do you have any other comments concerning the numerical magnitude of possible effects?

Dr. SELOVE. I would like to make one further brief remark, which I think may be of help to put these things in perspective.

We have talked here about numbers of individuals, such as 50,000 individuals in the world who may develop leukemia and bone cancer from tests so far.

To reduce these numbers to terms where one can more readily feel the impact they have on an individual, we might talk about the situation in, say, the city of Washington, or take Washington and Baltimore together, which I would say probably have a total population of perhaps 3 million.

In Washington and Baltimore together at the present time there are approximately 200 deaths per year from leukemia from normal causes. On the basis of the estimates that have been discussed here, one arrives at the conclusion that, for the next several decades, the results of fallout from tests so far will be that there will be, instead of 200 or so cases of leukemia a year, 202. So there will be that increase, from tests so far, in deaths from leukemia per year in a population of 3 million.

When this is translated to a country such as Japan, with a population of a hundred million, one finds that, instead of the normal 10,000 or so deaths from leukemia in Japan, there might be expected to be about 10,100; and translated into effects for the world as a whole, as compared to this 100 extra deaths in Japan per year, and 2 extra deaths in Washington and Baltimore per year, one comes to some 1,500 extra deaths in the world per year. And over 30 years that adds up to 50,000.

So one should look at all these numbers to try to get some perspective.

Fifty thousand. Is it many individuals?

In terms of impact on a parent in Washington or Baltimore, it means that if a child dies of leukemia, there may be one chance in a hundred that that particular death was due to fallout from tests so far.

Senator ANDERSON. Now, Doctor.

Dr. BRUES. I think perhaps, sir, if I read what was said in the report it may also clear up some other points.

Senator ANDERSON. You are talking about independence, and this is independent. You are perfectly free to do what you feel like. Go right ahead.

Dr. BRUES. The report said:

> Permissible dosage to large populations: This is a matter on which no complete agreement was reached by the subcommittee. First responses to this question ranged all the way from the permissible industrial level down to no radiation at all.

These were all people who have given a great deal of thought to the problem.

> The uncertainty existing here stems from our ignorance as to whether there is a true threshold for such late effects as malignant tumors, and as to the degree of variation in response of equally exposed individuals.
>
> It is agreed that the only rational approach must take into account the natural radiation background to which the population is exposed.

Then this is tabulated.

> It is noteworthy that considerable differences exist from place to place, due mainly to differences in gamma radiation from the environment and in part to

variation to radium content of individuals. Since these existing variations have not given rise to any changes in incidences of tumors or other pathologic states sufficient to attract attention, it was felt that an amount of internal radiation sufficient to double the large population background could certainly be considered safe.

Unfortunately, the word "safe" is in there, and I have less and less respect for the word "safe" as this discussion goes on.

Senator ANDERSON. Thank you very much.

Dr. Neuman, did you have a comment?

Dr. NEUMAN. No.

Senator ANDERSON. Does someone else have a comment?

Dr. Glass, you are a geneticist.

Dr. GLASS. I would like to comment on two matters that have been brought up already: One in respect to whether the genetics portion of the National Academy Committee's report is out of date, and whether an additional supplement is being planned.

We were so much impressed with the relative magnitude of the exposure of the population to X-rays from medical and dental diagnostic and therapeutic practice, in contrast to the relatively minor amount due to fallout on the basis of the current estimates, that most of our attention over the course of the past year has been devoted through our consultants to a more accurate estimation of the medical and dental exposure of the population to radiation; and the report on this study has been given a preliminary release already. I do not know whether it is in the hands of the committee or not, but it should receive general release soon.

As far as the conclusions in our report which relate to the effect of fallout are concerned, I might read that:

Since any additional radiation is genetically undesirable, the fallout dose is genetically undesirable.

Second, the fallout dose to date and its continuing value, if it is assumed that the weapons testing program will not be substantially increased, is a small one, as compared with the background, or as compared with the average exposure in the United States through medical X-rays. From the point of view of this committee, there are two summary remarks that should be made.

Senator ANDERSON. Any dose is undesirable, you say? Read that again, will you please?

Dr. GLASS (reading):

Since any additional radiation is genetically undesirable, the fallout dose is genetically undesirable.

Now, I believe that the testimony of the geneticists at these hearings is simply an amplification of those two statements, and that our position has not been changed at all. It is in accordance with the views that Dr. Libby has expressed. It is also in accord with the views that the geneticists expressed. It depends on how you look at these things.

Senator ANDERSON. Dr. Selove, I know you are in a hurry. Do you have a comment?

Dr. SELOVE. I am in complete agreement with what Dr. Glass has said. I think the genetics part of the report would probably not require serious modification.

I would like to repeat, however, that a very important factor in discussing levels in terms of a permissible level is the question of who decides what is permissible for whom. If it is a matter of a physician giving an X-ray to a patient, the physician decides whether the X-ray disadvantages are compensated for by the advantages.

If one of the several nuclear-testing powers in the world is subjecting the entire world to fallout, even in terms of very small percentage effects—and it is widely agreed, as Dr. Libby has said, that the scientific data indicate that the effects are only a small percentage increase over normal effects, even in such terms, the term "permissible level" implies that it is acceptable by the people subjected to it.

I think that is the important point on which further clarification is needed in the National Academy report.

I will have to leave. Thank you.

Senator ANDERSON. Dr. Machta, you had some calculations on uniformity and nonuniformity you were working on. Are those ready now?

Dr. MACHTA. Yes; if you would like to hear about them.

Mr. Hollister, do you have something else you thought should come first?

Mr. HOLLISTER. I had planned to go next into the strontium 90 question, but it is not necessary.

Senator ANDERSON. Go ahead, and we will come to this. Go ahead with the strontium 90 question.

Mr. HOLLISTER. I would like to do this with the understanding that, if time allows, we will come back to the question of MPC, and its setting later.

Senator ANDERSON. We probably will have time to get back.

Dr. GLASS. Mr. Chairman?

Senator ANDERSON. Dr. Glass.

Dr. GLASS. May I make one remark before we get too far away from the comments that Dr. Libby and Dr. Dunham made earlier?

I would like to testify personally to the complete freedom of investigators who receive support from the Atomic Energy Commission as to the direction of their own work, and also as to the choice of the problems on which they work. This is so important that, in the stepping up of the program, it actually becomes a problem.

The Atomic Energy Commission has leaned over backward to such an extent that it has never even suggested, except in the most informal and free way, to any person what kind of problems we really need answers to.

There is a need, as these hearings have brought out, for the answers to specific questions, which I hope we can find within the framework of the independence given investigators by the Atomic Energy Commission to encourage them to work on particular things.

Chairman DURHAM. Dr. Glass, of course, the reason the question arose was the fact that Dr. Libby said it should be stepped up, in his opinion, as I recall his statement. I think I am in complete agreement that there has been perfect freedom in this field of investigation. There was no implication of my thinking at all that it has been suppressed at any level.

Representative VAN ZANDT. Mr. Chairman, could we have Dr. Dunham fill that gap out?

Dr. LIBBY. Mr. Chairman, would it be in order to ask the people at the table here whether they agree with me about the need for additional emphasis on the biological effects of radiation?

Senator ANDERSON. I think it would be very much in line to do that. Why not just start around the table.

Dr. Libby said why do we not ask the panel whether they agree with him for the need of additional emphasis on the biological aspects.

Dr. Machta, do you want to comment?

Dr. MACHTA. I do not believe I am in a position to comment.

Senator ANDERSON. Dr. Neuman?

Dr. NEUMAN. Because you are not a biologist?

I feel a biologist is not qualified because he would obviously say "Yes."

Senator ANDERSON. We were talking about complete freedom, so we are going to allow a man to disqualify himself as a juror if he wishes to do so. If you wish to, Dr. Machta, we would be happy to have your comments.

Dr. MACHTA. I have no comment.

Senator ANDERSON. All right.

Dr. NEUMAN. I think it is very important, but how to go about it is also very important. I think we should not be swept away by the urgent need for information to just dump money into a program. Very careful consideration should be given to other aspects, such as future procurement of scientists, maybe not just in the field of biology, but also in many allied fields on which we are dependent. I guess that is all, except to urge careful study be made on the way you would proceed.

I would also say, in my own personal opinion, the Division of Biology and Medicine has certainly had a very balanced program, and certainly my own testimony attests to the freedom of scientists within the Division.

Senator ANDERSON. Would you not think, however, that an announcement by the Atomic Energy Commission that it felt this was a field in which there should be a speeding up might result in many other universities, such as Rochester University has done in this field, coming in and saying, "We would like to have a chance to do something, and here is what we would like to explore"?

Dr. NEUMAN. I think a policy statement would be very important; yes.

Senator ANDERSON. I think that is what I was trying to say.

If Dr. Libby made such an announcement across the country there might be many schools which have not taken part that might at least start to survey to see if there are any contributions they might make.

Dr. NEUMAN. I think from just reading the fallout information, a lot of people have not yet done that.

Senator BRICKER. Dr. Libby, are there many of these students that participate in the research programs in the universities—I know you have many that do—are there many of them who continue in the field or related fields to the atomic-energy program?

Dr. LIBBY. I think so. Our interests are so broad, Senator Bricker, that the answer to your question is undoubtedly "Yes." If they move from one discipline to another, the chances are we are interested in the other one, and they do not often move.

Senator BRICKER. They do not get very far away from the field?

Dr. LIBBY. No.

Senator BRICKER. Thank you.

Senator ANDERSON. Dr. Brues.

Dr. BRUES. I think Dr. Dunham and Dr. Libby are both well aware of the fact I have agreed with this point of view for some time, and

much of my concern has been how to implement, in an acceptable way, the progression of knowledge. Sometimes I think there are people who feel that the biological work is a small tail on the rather large animal.

It is true that you cannot expand biological work as you can a reactor program, just by drawing some designs and setting about it. But I fully agree.

Senator ANDERSON. Dr. Dunham.

Dr. DUNHAM. I do not know that I have anything to add to what these people have said. I think the suggestion of the AEC coming out with a fairly strong policy statement as to the needs in certain areas for scientists to work is a good one.

We have tried, as Dr. Glass indicated, through the staff of the division, by direct contact in talking with scientists as we travel around visiting our own projects, and attending meetings, to sort of seduce people into working on things we have felt were of primary importance.

As I will say later, I think we know, and particularly as a result of these hearings, have a better perspective on where the emphasis ought to be during the next few years.

Senator ANDERSON. Thank you.

Dr. Crow?

Dr. CROW. I agree. I have nothing further to say.

Senator ANDERSON. Dr. Warren?

Dr. WARREN. There are two added points that I would like to bring out.

First, I will say that I am in agreement with the other speakers in this field. However, I think one must guard against swinging a program to concentrate on any one phase of activity to a great extent. We have many other problems than the fallout problem with which to concern ourselves in the biological effects of radiation.

I feel that, while it is highly desirable to expand the research program in relation to fallout, there are many other aspects of the program which may be just as essential as fallout now is within a few years' time.

Senator BRICKER. For instance?

Dr. WARREN. Well, let me take the fallout thing itself. When our program was first started in the Atomic Energy Commission we examined very carefully the work that the Manhattan District had been carrying on, and the Manhattan District had very wisely become interested in the problem of strontium 90 quite early in its existence. We already had a backlog of information with regard to strontium 90.

There have been close to, I would say, 14 years of work already in this field, which has brought us up to the state of knowledge that we have at the present time, and makes a large program with regard to radioactive fallout a perfectly sound and reasonable thing at the present time.

Now there are problems in regard to the effect of alpha radiation, the effect of neutrons. There is the problem of how to protect individuals against radiation effects. There are a whole range of things which must not be overlooked in favor of one aspect of the program only.

I am very heartily in favor of an orderly expansion of the program with regard to fallout, but I would hate to see it at the expense of the present program, which I regard as a well-rounded and effective program.

Senator ANDERSON. Dr. Libby, you raised the question so you do not have to comment. Do you care to comment again now, or go on around?

Dr. LIBBY. No comment.

Senator ANDERSON. Mr. Eisenbud?

Mr. EISENBUD. As a nonbiologist who needs answers from biologists, I would heartily agree that some of these answers have got to be obtained before we can proceed much farther. On the other hand, I am impressed by Dr. Warren's remarks concerning the need for a balanced point of view.

I do not think it has been brought out in these hearings, Mr. Chairman, that one of the reasons why so many of these unanswered questions exist is because we know so much rather than so little. No substance to which human beings are exposed, either in the air or in the food that they eat has been investigated so thoroughly as radiation and radioactive materials. The total investment of the United States Government and private industry in the whole field of air pollution research has been something like $5 million in the last 5 years. Dr. Dunham can tell us how much has been spent in this field, but certainly it is in the order of $200 million or great in the last 5 years. It is simply characteristic of good research that answers beget questions, and for every answer that we find, we raise 1 or 2 or 3 new questions.

I feel intuitively that if we had full information about organic chemical heavy metals, and other things to which we are exposed in our environment, we should be asking the biologists many of the same kind of questions we are asking them today in regard to radiation effects.

Senator ANDERSON. Thank you, Doctor, for a very fine statement.

Senator BRICKER. I have not been able to follow the conclusions that some of you have reached. I have asked the question a time or two as to how much of the leukemia and how much of the bone cancer at the present time, regardless of imposed radiation, is due to the background radiation, and how much is due to other metabolic and biological factors, or facts. I have not had an answer to that question yet.

How in the name of sense are you able, from an indefinite base of that kind, to extrapolate, like one doctor did a moment ago, and say there would be 102 cases of leukemia in Baltimore and Washington, rather than a hundred cases, because of the imposed additional radiation from strontium 90? There is a gap in there someplace I have not been able to fill in in my own thinking. If somebody would explain it to me I would appreciate it.

Dr. WARREN. I do not think I can explain it entirely satisfactorily, Mr. Senator. But I would like to stress that when you establish a hypothesis, you can draw conclusions from that hypothesis, but, as you point out, those conclusions have no more validity than the hypothesis itself.

Senator BRICKER. No more validity than the hypothesis itself?

Dr. WARREN. And I think you will recall that I said on Monday I am not at all satisfied that strontium 90 will cause any additional cases of leukemia. I would think there is a possibility of an increased amount of bone cancer, but I am very skeptical as to leukemia.

This again, you might say, is only a hypothesis.

Senator ANDERSON. We did have, did we not, the statement from Dr. Selove yesterday, in which he quoted Dr. Lewis as saying that 5 to 10 percent of all present cases of leukemia are due to natural background radiation?

Dr. WARREN. I know of no way in which that can be established or proved, Mr. Anderson.

Senator ANDERSON. I do not know either. I just simply say that we have scientists who think they know.

Dr. WARREN. Yes. That is, I think that is a fair and reasonable assumption, but I do not think we are warranted in accepting it as an established fact.

Senator BRICKER. It is nothing more than an educated guess.

Senator ANDERSON. When you say, also, that one microcurie or one-tenth of a microcurie is a safe background, that is also an educated guess, is it not?

Dr. WARREN. No. I feel—well, yes, it is an educated guess.

Senator ANDERSON. Yes. That is right.

Dr. WARREN. But I think it has a little more foundation.

Senator ANDERSON. There is not a particle of difference between the two educated guesses.

Dr. WARREN. I think there is. If I could say one more word here. We know there is nothing unique about the radiation from strontium 90. We also know that there are much greater variations in radiations which have not produced clearly measurable effects. There may be some shadowy effects. We cannot say there are not any, but we can say there are none that are significant and measurable.

I would have no hesitancy in moving my family, myself, to your own State, sir, which happens to have a higher background, I believe, than Washington, and the strontium radiation is only a small part of this difference.

Senator ANDERSON. Now we are back on something we can agree on. I will be happy to say that I am willing to face a slight degree of leukemia and bone cancer for the privilege of living in my State.

Senator BRICKER. May I ask one more question?

Senator ANDERSON. Senator Bricker.

Senator BRICKER. On the assumption, Dr. Libby, or anyone else, that we had a hundred million dollars to spend in biological research this coming year, from what kind of an expenditure would you receive the greatest benefit, an expenditure in this field, or an expenditure in the field I think Dr. Eisenbud mentioned a minute ago, in the field of pollution of the atmosphere, the effect of automobile exhausts, smog in Los Angeles, and many other things that are present in contamination of foods, waters, and the like?

Have we neglected the one for the other? And should we give more attention to the general biological human effects of other deleterious things?

Dr. DUNHAM. My answer to that, Mr. Senator—anybody else can add their comments—we have not neglected one for the other. We have neglected the general effects you are talking about of all chemical

elements and things that are in the environment on man. I think that one should not, by that statement, then say that we should stop all work on radiation effects when we are just on the brink of learning a lot of important things that will help resolve some of the radiation problems. But there is no question but what the other activity dealing with all of these other substances about which we really know relatively little should be stepped up.

Senator BRICKER. You know there is one result of this meeting and this hearing—I think it has a good result generally—people are getting scared.

I said here a while ago that as a result of cigarette smoking and radiation, I am surprised we have got so many healthy people around. In other words, the other field is, to my mind, the more important in numbers, and we have overemphasized the radiation effects insofar as we know what they might be at the present time. I think we ought to turn some attention to the general and not neglect this, mind you, but we ought to give more attention to the general field of biology.

Dr. DUNHAM. I think there is no question about it, sir.

Senator ANDERSON. We got as far around as Dr. Glass.

Senator BRICKER. I am sorry.

Senator ANDERSON. I appreciate, Senator Bricker, your coming in here.

Dr. GLASS. I have already expressed myself on this question sufficiently in my testimony, I think, so I will just pass it on.

Senator ANDERSON. Dr. Langham?

Dr. LANGHAM. I had decided more or less what I was going to say until Mr. Bricker asked his question.

I do not think there is any doubt but that radiation has been the most emphasized environmental hazard that man has ever been subjected to. Why? Because it has a radioactive tag on it, which makes it easy to discover, and it is also new. Therefore, it has received considerable interest. So I would heartily agree with Mr. Bricker.

On the other hand, I would like to point out one thing which applies to radiation specifically, and perhaps to man's industrial environment in general, and that is that probably for the first time in the history of man he has advanced technologically to the point where he is beginning to become the weak link in what he can accomplish in the future.

I mean by that—let's take the human heart. It can wear out any mechanical pump of the same size that can be built by man.

If we want to, we can say that a man can ride a horse until it drops, or he can fly airplanes until they fall out of the sky with mechanical failure.

Now, however, we are reaching the point where man can build machines and gadgets in which he is the weak link in their operation. In fact, I might say that man has now reached the stage where he is the weak link in his ability to wage war, because he is reaching the point where in so doing he might even annihilate a large portion of his own population. This is even true of the man who wins the war.

So I would say, yes, by all means we should emphasize biological and medical or, let me say, human factors investigations. I do not mean we should do this without adequate planning, but I think we

should emphasize more the human factors in all aspects of our technological advancement.

I think for the first time radiation has called this to our attention.

Senator ANDERSON. Thank you very much, Dr. Langham.

We went around the circle. Now we shall start again by asking Dr. Machta if he wants now to present his information.

Chairman DURHAM. Mr. Chairman, I would assume from Dr. Langham's statement, then, that he believes it is a good thing for the human race that we do have radiation. Is that correct?

Dr. LANGHAM. Not necessarily.

Chairman DURHAM. Because of the fact that it has caused us to study all of these related things, such as biology and medicine and everything else. Now we have been studying the cancer cell here for generations. Of course, it is nothing new. We have failed to reach any decisions as to the cause of cancer prior to strontium 90 or prior to any fallout; had we not?

Dr. LANGHAM. Oh, yes, very definitely.

I would not say it is necessarily good that we have radiation, but I should say, also, that I do not think it necessarily means we have to stop further technological advancements because radiation is a factor in that advancement.

Chairman DURHAM. We have to have it.

Senator ANDERSON. I am very happy to see so many heads nodding in agreement. We are happy to find something on which these scientists agree.

Thank you, Dr. Langham, for producting that motion.

Chairman DURHAM. I raised the question because of the fact we have lived under sunshine here for thousands or millions of years, and we still have a future, I think. With the radiation that we are trying to determine—of course, that is the purpose of all of these hearings—can we continue to live with this thing, with the manmade process we have come to today? We have accepted the others for years because there was very little we could do about it.

Is that not essentially correct, or is it?

Dr. LANGHAM. You are very definitely correct. We have lived with many things in the past that are of our own doing.

For example, the smog from automobile exhaust. And I think we will continue to do it.

I am certainly in favor of saying we have faced many things that we have had to face because they were a part of our environment, and we could do nothing about them. We have also faced many things which are of our own creation in the interest of technological advancement. I say, yes, let's continue to face them, and by all means let's not think that radiation is the only one, and let's not think that radiation is the insurmountable one.

Chairman DURHAM. That is right. I agree with you.

Senator ANDERSON. Mr. Van Zandt.

Representative VAN ZANDT. Dr. Warren, did I understand you to say a moment ago that the data we have at the present time represents a spread of 40 years?

Dr. WARREN. It actually represents a still wider spread than that. We began to get some understanding of the effects of radiation in the late 1890's, very soon after the discovery of the X-rays, and the isolation of radium, and our knowledge of the field advanced very

slowly only recognizing the more extreme cases in the early days.

Then, with the concerted attack on the problems of atomic energy in the Manhattan project, there was added a great deal of additional information, which is being kept up and added to all over the world at the present time.

I also mentioned that there is one population in India on the Monazite sands which has lived there for many generations. We do not yet know the medical and biological effects of this, but these will be studied by the Indian Government, and the data made available to the world.

Senator BRICKER. Is there any indication that those people who did live in the Monazite hills have had a shorter life span?

Dr. WARREN. I do not believe that the vital statistics are sound enough——

Senator BRICKER. They are not sound enough yet to determine?

Dr. WARREN. To draw conclusions at the present time.

Senator BRICKER. Either on that, or leukemia or cancer?

Dr. WARREN. No. I think we will have to have pretty careful studies for a fairly long period of time to answer this.

Senator BRICKER. Are there not also some places in South America where the same conditions exist?

Dr. WARREN. Yes, there are. There are Monazite areas in Brazil. But here the inhabitants are chiefly Indian tribes who do not stay in any one area very long. And while studies are being carried out by the Brazilian Government, there will not be as large a population available for study.

Senator BRICKER. There is no evidence, is there, that there is any resistance in the human body built up to this radiation like there is to bacteria?

Dr. WARREN. No, there is no evidence there is any resistance. In fact, there seems to be an indication that, if there has been a significant amount of radiation given at one time, that individual will actually stand somewhat less radiation.

Senator BRICKER. Is that because of the accumulation or because of the weakening of the cells?

Dr. WARREN. That is probably because some of his cells have been injured or killed.

Senator BRICKER. Weakening, yes.

Senator ANDERSON. Now, Dr. Machta.

Dr. MACHTA. Do you want at this time to go into detailed numbers, sir? This is what has been suggested that I do.

Mr. RAMEY. In some detail. Not necessarily in absolute detail. I think the idea was that you made certain statements in your testimony last week, and from that information on the possible nonuniformity of deposits that you could make some calculations on future predictions of what might be deposited.

Dr. MACHTA. Thank you.

There are essentially three reasons why the fallout over the globe should be nonuniform. Two of these have never been in question. These are that tropospheric fallout from tests occurs primarily in the band of latitude in which the tests take place.

(Discussion off the record.)

Senator ANDERSON. Proceed.

Dr. MACHTA. I mentioned that there are essentially three reasons I believe why there might be nonuniform fallout over the globe. Two of these have never been in question and have been well accepted.

First, the tropospheric fallout occurs primarily in the band of latitude in which the test takes place.

Second, rainfall being the primary mechanism by which particles are removed from the atmosphere, will give rise to greater fallout in rainy areas than nonrainy areas.

The new element which has been added, and on which there may be some question, is the point I wish to talk about. This is the fact that fallout may be coming from the stratosphere preferentially in the temperature latitudes of Northern Hemisphere.

My contention is that I am not sure to what extent this occurs, and in view of the possibility, we ought to take into account a very conservative as well as, let us say, a very optimistic picture, in the hope that the truth will lie between the two.

What I would like to offer now are the numbers that one gets out of two pictures; one which essentially gives rise to complete uniformity from now on, and one which gives rise to extreme nonuniformity.

The latter is supposed to represent an absolute upper bound.

In order to compute my numbers, I have to make an assumption of the amount of debris still in the stratosphere, and from the previous testimony, up to mid-1956 there are still about 24 megatons equivalent of fission products left in the stratosphere. When it comes down, it will decay, and consequently there will be a smaller amount deposited on th ground. However, one might say that the tests which have been held since mid-1956 may balance the decay.

I can talk about two conditions: One, there are no more tests, and we want to find the fallout in terms of what has been put in the stratosphere already; and, second, the tests continue at whatever rate you wish to specify.

The curve which I drew several days ago describing the nonuniformity of fallout from all sources—and one need not ascribe it to either tropospheric or stratospheric fallout—shows about 10 millicuries per square mile as the average peak in the north temperate latitude as of 1956. If you have 24 megatons—this is equivalent to 12 millicuries per square mile when spread uniformly over the globe—by adding 10 and 12 one gets 22 millicuries per square mile in the north temperate latitude for the case of uniform future fallout.

Now, superimposed on——

Mr. RAMEY. How much is that in subshine units? Is it the same?

Dr. MACHTA. No; it is not the same.

Dr. LIBBY. You get the answer for the average soil pretty well by multiplying by two.

Dr. MACHTA. But these sunshine units are not in the human bone. There is still the discrimination factor.

Dr. LIBBY. These are sunshine units in the soil. So with Dr. Machta's 22, that is the average soil will be 40-some sunshine units.

Dr. MACHTA. This, then, would represent a sort of lower bound for the average temperate latitude of the amount that would have fallen out from tests conducted essentially to date. One can put this into perspective. According to the latest information, the norhern tier of the United States has about 33 millicuries per square mile.

However, superimposed on a value of 22 millicuries per square mile for the average band in the north temperate latitude, one should take into account the fact that there are areas of heavier rainfall than average. I have stated that the factor taking weather into account should be no more than 2 or 3. I think a reasonable number is two.

Therefore, I have suggested that the lower limit of the total fallout which will occur in the northern temperature latitude will be in the order of 40 or 45 millicuries per square mile, or converted to something under 90 sunshine units in the soil.

There is another way of looking at the matter. In a recent letter from Dr. Brewer, he suggests that stratospheric debris will come out almost entirely in the temperate latitudes of each hemisphere. This reasoning would yield a marked peak in the temperate latitudes.

The number I am about to quote is the upper bound. Mixing in the stratosphere must of necessity make this lower. I am not offering it as a number that would occur. I would like to make this clear. But since this an absolute extreme, the true number would be less than it.

The number I would like to offer is something of the order of 60 or 70 millicuries per square mile on the average. And again multiplying by the factor of 2, would bring the answer up to 120 or 140 millicuries per square mile.

As I say, I am not quoting this as a number we expect to have. This is a thing we can expect as the absolute upper bound.

This is what will happen from the tests to date. Fallout of strontium 90 will lie somewhere between 40 and 120 millicuries per square mile.

If we continue our tests at about the same rate, one can also make a calculation. Dr. Campbell, formerly of the National Academy of Sciences, has published an article in Science which shows how to take into account not only the radioactive decay, but the storage in the stratosphere. (See p. 1338.)

Presuming the test rate to continue at approximately 10 megatons per year—and if one desires any other test rate the answer is proportional to it. The assumption is made that the mean stratosphere storage time is 5 years—and I prefer this to 10 years, since it gives a slightly more conservative answer, although the difference is less than 10 percent, which is negligible. Then the answer at equilibrium, which will take many years to achieve, would be something in the order of 350 millicuries per square-mile or a little less, to something in the order of 850 millicuries per square mile. A very conservative picture is one in which the nonuniformity is no greater than a factor of 2 as the ratio of peak to average. A guess on my part—and I must admit this is a guess since I have not gone through any quantitative calculations—calls for a factor of 5 for the case of extreme nonuniformity for the ratio of peak to world average.

These give rise, as I indicated, to a range of 350 to 850 millicuries per square mile.

Mr. HOLLISTER. Is the concept of a mean storage time, in your mind a valid one for stratospheric fallout?

Dr. MACHTA. Well, meterologically speaking, it is not necessarily a valid one. I think it is useful for the purposes for which we are using it.

Mr. HOLLISTER. That is, empirically it is valid, although essentially we agree it offers some problems?

Dr. MACHTA. That is correct, sir.

Mr. HOLLISTER. The numbers 350 and 850 correspond essentially to equilibrium after a long period of time? Many years?

Dr. MACHTA. That is so.

Mr. HOLLISTER. Could we not say that within, shall we say, 35 to 100 years we will be so close to the equilibrium value that from then on we can say we are at equilibrium, assuming a constant rate?

Dr. MACHTA. I think this is roughly in the order of magnitude of time to achieve equilibrium; yes.

Mr. HOLLISTER. What is the factor you used to multiply by, to get this equilibrium number?

Dr. MACHTA. In the case of the most conservative picture, I assumed the peak was in the order of twice the average for the world. At the present time, the peak is something, I think, about two and one-half times the average of the world.

In the case of the least conservative picture, which I again view as an extreme and not likely to happen, it is of the order of five times the average for the world.

Mr. RAMEY. What are those figures, then, translated from your microcuries per square mile to bones, for example? Is that possible?

Dr. MACHTA. It is possible, if the gentleman here would provide the numbers. The first step would be to convert to subshine units in soil, which Dr. Libby has done very simply. The next step would be the discrimination factor. This I do not know how to do.

Mr. RAMEY. Perhaps we might carry on from there, and let possibly Dr. Libby, Dr. Neuman, or Dr. Eisenbud apply these discrimination factors, and see how we come out on these upper and lower limits.

Dr. NEUMAN. In my previous testimony, I said that my personal choice of the discrimination factor, and one that I thought represented the best guess, perhaps, was 8; and that I firmly believe the true discrimination factors lie between twice or half of these limits, between 4 and 16.

As far as I know, the other testimony of people using discrimination factors involved figures that also lay between these limits. I think some used 14.

I think, also, that this represents, as I mentioned, the view of Dr. John Lautit, of England. I believe he is on record as choosing eight for the present.

Really this is pretty good, considering some of the spread we have heard in statements. A factor of 2 is relatively good.

I think we are weak on estimates of effects, but in determining levels we can pretty well agree that it lies between 4 and 16.

Dr. LIBBY. I would comment on Dr. Machta's calculations as follows:

Dr. Machta and I agree that the question of the uniformity of stratospheric mixing is one that has to be settled by further experimentation.

There is a great deal of evidence for a certain amount of stratospheric mixing, as I remarked yesterday, since we do find strontium 90 in fallout, even at the South Pole and we have never found any place in the Southern Hemisphere where it rained at all where we did not find strontium 90.

So I think the extreme calculation is really rather extreme. It is all right to put it down, but I am sure Dr. Machta would agree it is rather an extreme calculation.

We will know this answer, as I said yesterday, by our stratospheric monitoring program. That is, we will know the matter of the horizontal mixing.

Now the possibility of concentration in terms of leakage at a certain latitude is an additional point which we will also learn about in connection with our studies of the age of the fission products that come down in our washtubs. We can determine simply whether the material that we collect is old or young. If it is coming from the stratosphere, it must be old; if it is coming from the troposphere, it must be young. And this program will settle it.

Representative VAN ZANDT. Dr. Libby could you include in your statement a time factor? And if that is not possible, will you know in a year or 2 years?

Dr. LIBBY. I think we will know in less than a year. Maybe I am being optimistic, but a year ago we would not have made the flat statement that rain is it, as far as fallout is concerned. And we all make it now. We have established that firmly, we think, during this past year. I think so.

Representative VAN ZANDT. Can you definitely establish the age of the fallout?

Dr. LIBBY. Yes, sir. It is not the easiest thing in the world to do, and it has not been done very often, but it can be done.

Representative COLE. Does not this fallout have any weight at all?

Dr. LIBBY. No, sir.

Representative COLE. None whatever?

Dr. LIBBY. Negligible. We think the particle size is so small you cannot see them, even by the highest powered microscope. We think the particle sizes are well down in the hundredths of a micron range. They may be as large as a tenth of a micron. They are very, very tiny, too small to see, but we can measure them by virtue of their radioactivity.

Now the matter of the discrimination factor. I would not argue with as eminent an authority as Dr. Neuman, and I certainly think his statement is a fair one from all that I know about this difficult subject, that the discrimination factor between average American diets and the bones should be between 4 and 16. I think certainly that must be right.

There is one little point I would like to make that seems not to have been made by anyone. I think it is just accident.

We find the fallout in the top 2½ inches of the soil; therefore, deep-rooted vegetables get less strontium. This is a point worth thinking about. If you plow it to distribute it, it will still get less strontium, for there will be more calcium to dilute it.

So the short-rooted grasses which produce the milk give us about the worest situation.

So I think there is another factor. It is not what we should call a discrimination factor, I think, in the human body, but there is a sort of physical factor as to the depths of the strontium 90 deposits relative to the length of the roots which pick it out of the soil. I do not know what that number should be, but I think it is certainly a significant number.

Maybe like—I do not know. Certainly a number greater than 1, and probably less than 2. So there is a factor which could be multiplied by the discrimination factor which Dr. Neuman gives.

Senator ANDERSON. Mr. Hollister.

Mr. HOLLISTER. Dr. Libby, then you would agree that we should use equilibrium discrimination factors at the moment rather than, for example, to try to relate soil data to, let us say, Kulp's bone data?

Dr. LIBBY. I think you should do both, Mr. Hollister. That is, you should figure out—we know now, as Dr. Kulp has said, that fresh bone is, I think he testified, 0.7 sunshine units in this country, and this at a time when the average soil was—well, it is hard to say just when the children got their average food—but say, 50 sunshine units. Between 40 and 50 sunshine units probably was the ground concentration.

Now all of these factors have come in to give us a ratio in excess of 50 between the ground concentration and new bone at the present time.

Now, the equilibrium discrimination factors are only part of it. I just mentioned another one.

There is another factor I have not mentioned, and that is that the Imperial Valley and desert regions supply truck crops through irrigation methods where the strontium 90 is lower. So this leads to a decrease in the strontium 90 content of the average diet, you see. That should be in.

Mr. HOLLISTER. I am going to go from an MPC in the body, and let's beg the question whether there is one at the moment. If I want to go from MPC to testing rate, which I think Dr. Neuman showed we could do in principle——

Dr. LIBBY. Yes.

Mr. HOLLISTER. How do we get there? Do we go by way of a factor of 50 or 30, or by a factor of 8?

Dr. LIBBY. I do not think we know the right answer to that question. I think you had better do both of these calculations. It looks to me like we have to admit to a certain ignorance as to the correct way. That is, we have 4 to 16 as the range here. I really think Dr. Neuman knows the factor a little better. But that is a fair range. Then we have to estimate these various additional things I have mentioned, and there are some unknowns in this calculation.

Mr. HOLLISTER. Could I ask Dr. Neuman to comment here?
